A call from any fixed telephone in the network to a mobile unit is made by obtaining the mobile operator in the usual way and giving her the telephone number of the car being called. The operator dials this number which causes alternate pulses of 600 and 1,500 cycles to be sent out, thereby operating the selector unit associated with the receivers of all mobile units within range of the transmitter but only the selector adjusted for the code being dialed will close a contact to ring a bell and light a lamp in the desired vehicle.

The general mobile service has filled an important need, the demand already having exceeded the number which can be handled over presently available frequency assignments in the larger cities. It has been estimated that a large metropolitan area like New York might require 150 channels, each handling about 75 vehicles, to take care of the demand for mobile service over the next few years. A few examples of the types of customers who are using mobile service are ambulances, automobile service companies, small boat operators, burglar and fire alarm services, public utility companies, police and fire departments, newspapers, physicians and trucking services. Systems using the same types of equipment and operating in the same frequency range are also used to serve vessels in harbors, lakes, and rivers.

Telephone service to passengers on railroad trains was started on August 15, 1947 with several trains on the New York-to-Washington run equipped for the service. Initially the service is being given through the general mobile systems located in the several large cities on this route. The arrangements on the train differ considerably from those generally used in automobiles in that the push-to-talk switch is eliminated in order to make the service as easy to use as a telephone in one's home. This requires that the radio transmitter and receiver in the train be operated simultaneously which is accomplished by using separate antennas for transmitting and receiving and introducing a radio frequency filter in the receiver to discriminate against the transmitting frequency.

Consideration is being given also to providing telephone service for passengers on some airplanes. This involves special problems in that the plane travels so very rapidly and, because of its elevation, may cause interference to receivers located hundreds of miles away.

Domestic Point-to-Point Radiotelephony

The use of radiotelephone for point-to-point communication within the United States until recently has been on a relatively small scale. As long as radio was limited to the lower frequency ranges, the small number of channels which were available had to be reserved for mobile and overseas services and other situations where wire telephony could not be employed. As new frequency ranges were opened and vastly larger numbers of channel assignments became available, the application of radiotelephony could be extended from situations where wire telephony was impossible to cases where it was impracticable, then to cases where it was difficult and, perhaps, in the future to situations where wire is less economical.

Emergency Radio

The use of radiotelephone for emergency point-to-point communication when wire lines are disabled by storm or flood, came early in the foregoing scale of radio applications. For this purpose about 100 portable transmitting and receiving stations have been made available and these are stored when not in use at strategic points throughout the United States. These sets operate on a single frequency in the 2-megacycle band and employ a transmitter having a power output of about 50 watts. The receiver is normally connected to the antenna, but when speech is applied from the wire circuit, a voice-operated relay switches the antenna to the transmitter and energizes the transmitter. Arrangements are included to permit connection to various types of wire line and to handle several types of signaling. Generally each of these emergency sets is mounted in a small trailer along with all arrangements necessary to make it a self-contained unit, including a gasoline-driven generator to provide power. The trailer is light enough so that it can be pulled by an ordinary passenger car and can be moved by hand for

Figure 12. Telephone set and control unit in automobile

Figure 13 (left). Emergency radiotelephone installation in trailer

Figure 14. Antenna installation for experimental rural radiotelephone installation at a ranch

short distances to obtain desirable final locations. Figure 13 shows one of these trailer-mounted emergency sets in operation.

An illustration of the use of this equipment was the occasion when the communities of Denison, Whitesboro, and Gainesville in north central Texas were isolated from the telephone network by an ice storm which destroyed the wire lines. Two of the emergency radio systems were quickly placed in operation, and some 640 telephone messages were handled in this manner during a 6-day period while wire circuits were being restored. A number of such uses occur each year.

Point-to-Point Radio in the 30 to 300 Megacycle Band

In 1934 a radiotelephone installation operating in the 60-megacycle region was installed between Provincetown on Cape Cod and a point near Boston. A few additional single channel systems have since been installed to reach islands and other points which are inaccessible to wire lines.

In 1941 a 12-channel system operating in the 160-megacycle range was installed between Ocean View and Cape Charles to provide circuits terminating at Norfolk from points on the eastern shore of Chesapeake Bay. This 25-mile radio link was an alternative to providing wire circuits which would go around Chesapeake Bay, a total distance of over 200 miles, or submarine cables subject to frequent damage since they would cross a very busy ship channel.

An interesting recent use of radio for point-to-point service and one of the first applications of frequency modulation for this type of service, was in Death Valley, Calif. This region is isolated from inhabited areas by vast stretches of deserts. Telephone service had previously been provided over a wire line along a railroad which was used to haul out the borax which was mined in Death Valley. This railroad has been abandoned, with the result that the wire line is inaccessible for maintenance purposes. Radio systems, therefore, were used to connect Death Valley to an important open-wire line which passes about 25 miles away. They operate in the 150-megacycle range and each system can provide three telephone channels.

Another use of point-to-point radio is an experimental system to serve a group of isolated cattle ranches in Colorado. One end of the radio circuit is located at a small central office and this provides communication to eight ranches on a party line basis, radio equipment being located at four of these ranches and the others being connected to one of the radio stations by wire extensions. The antenna installation on a ranch is shown in Figure 14. This equipment operates in 50-megacycle range and is arranged to operate from the customer's standpoint just as though the telephones were served by rural wire lines. During a severe snow storm in its first winter of use this radio system proved invaluable in obtaining emergency help.

Microwave Point-to-Point Systems

As has been previously outlined, radio started in the early 1920's with frequencies as low as 60 kcs. Step by step the art

Figure 15. New York-Boston radio relay system

Figure 16. Repeater station in New York-Boston radio relay system, showing lens antennas

advanced into the higher frequency ranges and reached about 20 megacycles in the late 1920's and went on beyond 100 megacycles in the 1930's. Each advance has greatly increased the number of channels available and has brought radio nearer to wire lines in transmission performance. With the most recent advance into the region of thousands of megacycles, radio energy can be directed along narrow paths, atmospheric and man-made noise is very low or nonexistent, the variation in transmission loss is sufficiently limited that it generally can be compensated for by regulating arrangements, and large numbers of channels are available. These characteristics so nearly approach those of wire that it is possible that in the future radio will be used in many cases where wire has previously had a clear field. Also, many of the techniques which have been devised to extend wire transmission over great distances, such as intermediate amplifiers at regular intervals to overcome path losses, can be employed for radio operating in these frequency ranges.

Catalina Island, which saw the first commercial application of radiotelephony, has again become involved in another pioneering use of radio. During 1946 an 8-channel pulse modulated radiotelephone system operating in the 4,500-megacycle range was installed between Los Angeles and Catalina Island, a distance of about 50 miles. The radio beam is sharply directed by means of parabolic antennas, permitting the use of transmitting power of only a few watts. A similar system has been installed between the mainland and Nantucket Island on the east coast of the United States and a 2-link system providing 16 channels by the same method has been placed in service to span a distance of about 115 miles in very mountainous country between Marysville and Redding, Calif.

In order to determine the field of use of microwave radio in the commercial communication network of the United States, a full-scale radio relay system has been set up between New York and Boston, a distance of more than 200 miles. This trial system employs seven intermediate radio relay stations with a clear line-of-sight path between adjacent stations. Two radio channels are provided in each direction, one for service and one standby. Frequencies in the vicinity of 4,000 megacycles are used and the frequency used for a particular channel is shifted by 40 megacycles in passing through a repeater station. For a given channel the same radio frequency is used in alternate repeater sections. In the repeater most of the amplification is provided at an intermediate frequency of 65 megaycycles, but the final amplifier operates at the radio frequency of about 4,000 megacycles and employs velocity variation tubes. The transmitted power is of the order of one watt and this power is directed toward the adjacent station by means of a shielded lens antenna having an aperture ten feet square to focus the radio energy into a beam sharper than that produced by a searchlight. Each of these antennas provides a power gain of more than 8,000-fold (39 decibels) over an isotropic radiator. Each radio channel provides a communications channel four or five megacycles wide, and this broad channel can be used for television transmission or for hundreds of telephone channels. Various methods of using this broad channel for many telephone circuits are being tried out, including frequency division and time division.

Figure 15 shows the location of the repeater stations between New York and Boston and Figure 16 pictures one of these stations, with the shielded lens antennas showing prominently. One antenna is used for transmitting and one for receiving in each direction of transmission. The same antenna is used for two channels and it is possible by means of band pass filters to combine still more broad channels for transmission through the same antennas. In addition to the radio equipment, the relay station includes emergency power equipment which functions to keep the station in operation even though the outside source of power should fail.

Plans are well under way for similar radio relay systems from New York to Chicago and along other routes.

When Marconi demonstrated radio 50 years ago, its first application was for transmitting intelligence by means of a telegraphic code consisting of a series of short pulses. Since that time many other methods of using radio for the transmission of intelligence have been developed and applied, but recent developments again use a code made up of short pulses, this time for the transmission of speech. In one system of pulse code modulation, samples of a speech wave are taken 8,000 times a second and each sample is translated into a 7-unit code which carries over the radio circuit information as to the magnitude of the sample, thus permitting the speech wave to be reconstructed at the receiving end. Systems have been built in the laboratory in which information as to samples from 100 different speech channels may be transmitted over the same radio channel on a time sharing basis. The advantage of such a system is that there can be great disturbances, variations, and distortions in the transmission medium without affecting the quality of the speech, since it is only necessary to determine at the receiver whether the signal is present or absent, with no gradations in between, in order to perfectly reconstruct the original speech signal. Furthermore, the signal can be regenerated just as telegraph signals are regenerated, thus permitting transmission through many relay stations without degradation. It is interesting that in the past 50 years we have made a complete circle in coming back to something like the telegraphic code used by Marconi, except that now we send millions of signal pulses each second instead of tens of pulses. During only a little more than half of the 50-year interval since Marconi's celebrated demonstration has the medium of radio been utilized for commercial telephone purposes. Not only has the length of individual radiotelephone links increased enormously since the establishment of the short 32-mile link between Catalina Island and the California mainland, but also the variety of places reached by radiotelephone has been multiplied. Much opportunity for development clearly lies ahead in this field, and the part that radio will play in world communications 50 years hence is indeed a fascinating subject for speculation.

The Bellingham Hydraulic Log Barker

V. C. HANER
NONMEMBER AIEE

H. A. ROSE
MEMBER AIEE

IN THE PRODUCTION of the higher grades of wood pulps, used in the manufacture of paper and other products, it is necessary to remove the bark from the logs as the initial process in the preparation of the wood for manufacture into pulp.

Phenomenal savings in valuable pulp wood and labor are being realized by the Pacific northwest pulp and paper mills, Figure 1, through the use of modern full-sized-log debarking machines. The larger of these machines are capable of debarking run-of-the woods sized logs of to 80 inches in diameter "bucked" to lengths approximating 20 feet. So successful has been the experienced gained with the latest type of these large size debarkers in handling even the small logs that increased attention is presently being given to the building of smaller units designed specifically for mills requiring less production or where short lengths, small diameters, or "farmer wood" may prevail.

The older methods of debarking small cut-up sections of the tree, by tumbling them together in revolving drums or by passing the sections under the knives of high-speed barking machines is rapidly becoming obsolete. Modern northwest wood preparation plants utilizing large full-size-log hydraulic barkers and chippers[1] are realizing savings in valuable pulp wood in the order of 20 per cent over the older wasteful methods. It is expected that increasing use will be made of still larger hydraulic barkers in large saw mills for removing the bark of the logs prior to their reaching the head saw, to improve the yield in lumber, conserve by-product pulp wood and to reduce saw maintenance and mill clean-up expenses.

Paper 48-196, recommended by the AIEE general industry applications committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 3, 1948; made available for printing June 17, 1948.

V. C. Haner is plant engineer with the Puget Sound Pulp and Timber Company, Bellingham, Wash., and H. A. Rose is consulting and application engineer with the Westinghouse Electric Corporation, Seattle, Wash.

Types of Big-Log Hydraulic "Barkers"

This paper will deal primarily with the electrical engineer's problems, applying to the new currently known Bellingham-type of big-log hydraulic barker developed by the engineers[2] of the Puget Sound Pulp and Timber Company of Bellingham, Wash. It is felt however that brief mention and review should be made of the other three principal types of big-log hydraulic barkers which preceded the Bellingham type during the past five years, all of which are presently in successful operation in mills of the Pacific northwest.

All of these barkers make use of a large quantity of high-pressure water directed against the log by a suitably-designed nozzle or system of jets. By appropriate electrical controls the nozzle and log are each moved with respect to the other so that the full area of bark is covered. The force of the powerful jets blast and wear away the bark, leaving a clean wood surface. An operator called the barkerman is required to manipulate the various controls whereby the logs are loaded into the machine where they are barked and finally unloaded or removed from the machine.

The Lathe-Type Barker

In this barker the log is chucked between centers of a lathe-type arrangement by which rotary motion is imparted to it. The nozzle which is positioned from above is held by the force of gravity at correct distance from the log by a shoe which rides on the bark. As the log turns the nozzle is caused to move along the log axis and the bark is removed in a way similar to the operation in a simple wood lathe.

The Log Indexing Barker

In this barker the log is firmly held by a surrounding collapsible set of chains which grips and imparts to it either an indexing or slow continuous rotational movement. The nozzle is positioned under the log and is rapidly reciprocated for the full length of the log. The log has been barked by this continuous stripping action when it has made one complete revolution.

The Adjustable Ring Barker

In this barker the logs travel butt to butt through an adjustable diameter ring-type segmental nozzle designed to cover the periphery of the log. Water is released at the instant a log enters the ring and is shut off as soon as the trailing end has passed through. For logs larger than a certain diameter the segmental nozzle does not make complete coverage which results in strips of bark being left. To remove these, the log is indexed or turned the required amount and reversed through the machine.

The Bellingham Barker

In the Bellingham barker the logs are supported in and caused to revolve by two adjacent sets of trunnion rolls, Figure 2. A nozzle supported from above is driven along the axis of the log as it turns. The jet removes the bark in a manner quite similar to that in the lathe-type barker. Figures 3 and 4 show the principal elements and layout of a typical Bellingham type of barker plant.

The logs as received from the pond, Figure 5, are first cut to length by the cut-off saw, Figure 6, ahead of the barker. From the saw they are passed to the fore deck at the entrance of the barker by approach chains under the control of the barkerman. They are prevented from entering the trunnion rolls by stop arms which form a part of the loader system. The approach chains may operate more or less continuously by slipping under the logs as held back by the loader.

Figure 3. Typical layout of Bellingham-type barker plant

View facing side of log

Assume that the barkerman has placed all auxiliary machinery in operation preparatory to barking. He first starts rotation of the empty trunnions at a speed suitable for the particular log held at the loader. By a thumb button on one of the control levers of the control desk, Figure 7, he causes the unloader to move to the raised position presenting the unloader sectors as knees to the incoming log. If necessary, he elevates the nozzle by a "raise" thumb button to a height such that it will not be struck by the incoming log. He next operates the loader which simultaneously starts a log rolling into the trunnions and throws a block against the release of other logs. The loader is then allowed to retrieve, permitting advance of the next log to be barked.

The entering log is prevented from rolling past the trunnions by striking the knees of the unloader. It immediately starts to accelerate to trunnion speed as the barkerman retrieves the unloader. He next lowers the nozzle if this is necessary, by appropriate thumb button. He has previously estimated and set the approximate speed at which the nozzle is to traverse the log. By operation of a "forward" thumb button on the nozzle control lever the nozzle is caused to traverse the log. It automatically stops at the opposite end. The barking of this log is now complete. He again energizes the unloader which ejects the barked log to the after deck, see Figure 8.

If in the meantime he has transferred his controls for "automatic loading" another log will be automatically started into the trunnions and the procedure will be repeated but with reverse travel of the nozzle carriage. These and other operations are built into the barkerman's controls in such a way that minimum effort is required to manipulate them. Proficiency is mastered after a short training period so that several hundred logs can be easily barked in an eight-hour shift.

Barker Sizes and Barked Log Production

The size of the Bellingham barker is determined principally by the diameter

Figure 5 (left). Fifty-inch diameter log on log slip on the way to the cut-off saw

Figure 7. Barkerman's control desk showing operating levers and auxiliary equipment push button control section

and length of the largest log that is to be handled. The V formed by the trunnions must be large enough to maintain stability when logs of usual deformity revolved at moderate speeds. Eighty-inch logs require about 48-inch diameter trunnions. Sixty-inch logs can be handled in 36-inch trunnions. The number of trunnion rolls must be sufficient to afford reliable turning effort for deformed and crooked logs, and arranged so that short logs can be barked at full pressure without too great a tendency to up-end from the force of the jet.

The production or output of the barker depends upon the speed of log rotation and the length of the nozzle jet. The nozzle can advance no more than one nozzle length per revolution of the log, otherwise threading will result in bark being left on the log. Overlapping may in certain cases be required when bark is difficult to remove, but in all other cases it represents a loss of production. In practice a certain degree of overlapping occurs at all times which is partly compensated for by the natural tendency of the jet to widen or flare in passage to the log. About 500 feet per minute of log surface speed is considered an upper practical limit for log rotation. With about 75 gallons per minute per inch of nozzle length, and in the order of 1,200 to 1,300 pounds per square inch water pressure, very satisfactory barking action is obtained for all species and conditions of Pacific northwest trees.

Based on perfect co-ordination between revolutions per minute of the log and nozzle advance, the production or output of the barker is:

$$\text{Production in cubic feet per hour} = 0.104\ RLDE$$

where

R = surface speed of log in feet per minute
L = nozzle length in inches
D = mean diameter of log in inches
E = barking efficiency
S = free running nozzle speed in feet per minute

The efficiency factor E recognizes the impossibility of maintaining the jet at 100 per cent barking speed S and accounts for all time lost in accelerating and decelerating the carriage, rebarking loading and unloading, overlapping and so forth. For the usual application E may be taken as 0.5.

For any nozzle speed less than the critical speed the production is:

$$\text{Production in cubic feet per hour} = 0.328\ D^2SE$$

For short lengths and small log measure it is sometimes desirable to refer to the barker output in terms of stacked cords. If the relation between solid wood and stacked volume for the cord is taken as $\pi/4$, the solid cubic contents of the cord becomes $4 \times 4 \times 8 \times \pi/4 \cong 100$ cubic feet.

Figure 8. Barked logs at the exit of the barker on way to whole log chipper

Figure 6. Nine-foot circular cut-off saw cuts logs to proper length for the hydraulic barker

Figure 9 (left). Production chart for Bellingham barkers having different nozzle lengths, trunnion diameters, and speeds

Figure 10. A 24-inch 1,300 pounds per square inch nozzle and jet removing bark from a 20-foot log

Figure 9 relates the various production factors discussed and gives the barker output in 100's of cubic feet per hour≅solid cords per hour, at an assumed nozzle speed-efficiency E of 50 per cent. The third quadrant is for relating the log and machinery speeds and includes the full range of log sizes encountered. The first quadrant is for determining production output and includes only the smaller log diameters. Scaling of many thousands of logs delivered to the mills shows that for run-of-the-woods logs, the arithmetical and/or weighted average size will be in the range of 15-to-20 inch diameter.

Figure 9 gives barker production in solid cubic feet measure. The values as read from it may be converted to Brereton[1] scale-board feet measure by multiplying the number of cubic feet produced by 12. To obtain the corresponding Scribner decimal C, Spaulding, and British Columbia[3] scale-rule values it will be found sufficiently accurate for barker application purposes to take 60 per cent of the calculated Brereton values.

Water Supply for the Barking Nozzle

Basically, bark removal is brought about by the combined effects of erosion and blast from the impinging force or jet action of water at high velocity applied to a small area of bark surface, see Figure 10. Within the range of effective barking pressures and practical log rotation speeds, the bark removing ability of the jet can be taken to vary as the product of mass and velocity per unit length of nozzle. In practice these quantities are usually expressed as flow in gallons per minute per unit length of the barking nozzle (representing mass) and the square root of the orifice pressure in pounds per square inch (representing velocity).

The quantity of water required by a particular nozzle for effective barking will depend upon its design. In general, slot-type nozzles, Figure 10, having about 50-thousandths-inch slot width require from 65 to 80 gallons per minute per inch at a working pressure of 1,100 to 1,300 pounds per square inch.

A 50/1,000-inch nozzle delivering approximately 80 gallons per minute per inch at 1,300 pounds per square inch will remove the most difficult bark from northwest logs, as occasioned by cutting the trees during the dormant winter months.

Multi-stage high-pressure induction motor driven 3,570-rpm centrifugal pumps, Figure 11, are used to feed the nozzle. Small 6-inch nozzle barkers require about 500 horsepower to drive a single pump. A 24-inch nozzle will require at least two 800-horsepower pump sets. Induction motors of this type and speed will take about 550 per cent of full load kilovolt-amperes when started at full voltage across the line. For mills having somewhat limited capacity, reduced voltage starting may be required to minimize disturbance to other equipment.

Steam turbines make very desirable and economical drives for these pumps when the heat balance of the mill justifies their application. Turbines have an advantage of adjustable speed by which comparatively easy summer-cut log barking conditions may be handled at reduced water pressure with consequent saving in energy.

The Log Roll Drive Unit

The log-roll motor is connected directly to the trunnion rolls through a speed reducer and chain sprocket drive. The motor must be capable of starting, revolving, and tumbling logs of all shapes and sizes that come within the capacity of the barker. The speed range required of the trunnions will vary from a "creep" for the largest poorly shaped logs to about 40 rpm depending upon the application. About 500 feet per minute of log surface speed is considered to be the upper practical limit of log turning and economical barking speed.

The resistance offered by the bark in its removal varies with the kind and age of the trees, the climatic conditions under which they were grown, the thickness of the bark, the season of the year when cut and the time between cutting and barking. These factors largely determine the upper limit of surface barking speed for a given rate of water flow per inch of nozzle length, within the ranges of effective barking pressure.

A direct current, reversing, variable voltage, adjustable speed shunt motor and gear unit, powered from a reversible polarity adjustable voltage power supply generator usually provides the most satisfactory type of drive for the trunnion rolls for the larger barker units, Figure 12. About ten equal speed steps from near zero to full speed can be obtained economically with this type system and materially assists in obtaining maximum output from the barker. This system permits carrying large currents to produce high torque at low speeds which is often required for the larger sized logs. A per-

Figure 11. Two 800-horsepower, 1,300 pounds per square inch 3,750-rpm pump sets for nozzle water supply

Figure 12. Power and control circuit schematic diagram for d-c variable voltage nozzle carriage and trunnion roll drives with induction motor nozzle hoist drive

fectly shaped 60-inch diameter 20-foot hemlock log from the pond may weigh 17 to 18,000 pounds, representing considerable dead weight and shear friction loading against the trunnions. This loading is very greatly increased when poorly shaped logs having elliptical or odd-shaped butts are encountered as these result in partial displacement of the center of gravity when rotating, and produce locking effects in the trunnions. It is often necessary to start such logs from rest or to reverse-roll them to clear out rot and crevasse.

This requires that the motor be capable of lifting a portion of the log weight in addition to overcoming the friction and shear loading. To provide for these indeterminate loading factors, experience to date indicates that under stalled conditions the motor torque should be capable of exerting a force against the log equal to about 25 per cent of the log weight.

Four-speed constant torque-type squirrel cage induction motors with reversing control have been considered for the larger barker roll drives. To date none of these have been built. However, two small sized barkers are on order which make use of this type drive.

The a-c motor drive is usually somewhat less expensive than the d-c drive and is given preference for this reason. In such cases, it is considered practical to "buck" the largest poorly shaped logs to shorter lengths so they can be more satisfactorily handled and at less overload requirements on the motor.

Large poorly-shaped logs and generally bad timber conditions may require a large percentage of slow-speed high-torque trunnion motor operation. Forced air ventilation of the roll motor may be required for such application. If found necessary this can usually be added without appreciable cost.

Nozzle Carriage Drive Unit

The carriage drive motor is connected to the load through a speed reducer and propulsion cable drum. The cable is attached to both ends of the nozzle carriage over a pulley system which permits driving the carriage in both directions by reeling and unreeling of the drum.

The production output of the barker is directly related to the acceleration, deceleration, and reversible speed characteristics of the carriage drive. Upon being released to travel the carriage should quickly accelerate to the speed selected by the barkerman. This speed should be maintained to the end of the carriage track where equally rapid deceleration causes it to stop. If occasion demands the carriage should be capable of rapidly stopping, starting, and retracking over any portion of the log length to pick up missed bark, clear away rot, or clean difficult sections of the log. In general the carriage should have the feel at the controls of being alive as opposed to that of sluggishness.

For low-production barkers the rates of acceleration and reversibility may not be of great importance. For high production units these become of prime importance in determining the output for a given eight-hour shift. These and other factors can easily determine the number of barking shifts required to match the mill's average chip requirements.

A direct current, reversing, variable-voltage adjustable-speed shunt motor and gear unit powered from a reversible polarity adjustable voltage power supply generator is the correct type of drive for this system. The design should provide for all carriage speeds from a slow creep to the maximum speed as set by the smallest log diameter and nozzle length. The number of equally divided speed steps within these limits may vary with the particular application but in general ten steps will be found adequate.

The maximum speed of the carriage is determined by the maximum speed in revolutions per minute which is considered practical to rotate the smallest log. If excessive speeds of rotation are given to the smaller logs they tend to jump and ride away from the trunnions. Perfect specimens are subject to little of this tendency. For 6-inch diameter logs between 250 to 300 rpm is usually a reasonable upper limit considering the small number of such logs that come in normal production. Assuming no overlapping of the barking jet the maximum speed of the nozzle carriage in feet per minute is:

S = (revolutions per minute of smallest log) (nozzle length in feet)

Figure 13. Maximum inertia and friction horsepower developed for different carriage weights and speeds

Figure 14. Ratio between maximum horsepower and root-mean-square horsepower for 8,000 pound carriage with 20 feet travel for different accelerating rates

Figure 15. Nozzle carriage, showing nozzle elevating mechanism and cable flexible high-pressure hose, swing pipe, supply pipes, and propulsion cables

Figure 16. Automatic control cabinet for barker controls, resistors, and protective relays

In the usual application the barker will be designed to handle run-of-the-woods size logs which may for example vary from 6 to 60 inches diameter. The top speed of the carriage should in most cases be based more nearly on the speed of the arithmetical size log or the weighted average size based on wood content. This practical consideration may avoid fictitious calculated requirements for excessive carriage speeds.

For applications where the barker is designed to handle only small size logs higher values of log rotation and carriage speeds may be justified. The factors relating the application to the power characteristics required of the drive are all tangible and lend themselves to easy calculation. The following approach to determine the power requirements and rating of the motor has proved satisfactory.

Assuming uniform carriage acceleration

$$F=\frac{W}{g}a$$

$$a=\frac{S}{60\Delta T}$$

The maximum horse power developed by the motor in overcoming inertia to accelerate the carriage becomes

$$HP_i=\frac{FS}{33{,}000}=\frac{WS^2}{63{,}700{,}000\,\Delta T}$$

The maximum horsepower required to overcome friction is

$$HP_f=\frac{W_e S}{33{,}000}$$

Where

F = force in pounds
S = free running carriage speed in feet per minute
a = acceleration in feet per second per second
W = weight of nozzle carriage complete in pounds
e = coefficient of rolling friction
ΔT = the time in seconds required for acceleration

e is usually based on 50 pounds per ton of carriage weight to give a friction constant of 0.025. The total maximum horsepower required of the motor is then HP_i+HP_f.

This method intentionally assumes that the maximum requirements of the motor will be determined by its ability to commutate the currents established by acceleration as modified by the root mean square horsepower of the duty cycle if this later correction is required.

Figure 13 gives the inertia and friction horsepower for different carriage weights and speeds for an accelerating time ΔT of one second. In figuring the horsepower required for high production barkers the accelerating and decelerating time is usually taken as 0.5 second which doubles the inertia horsepower values given by the chart.

It will usually be desirable to check the root mean square horsepower loading for the particular duty cycle imposed by the carriage movements. The time intervals for the various movements may be established by conventional calculation assuming constant and equal acceleration and deceleration rates. The carriage should be considered to travel a distance equal to the maximum log length plus two times the nozzle length. This allows the nozzle sufficient travel to clear the log on each end. These calculations have been made for an 8,000 pound carriage based on 20 feet total travel for ΔT equal to 0.5 and one second and expressed in 1/1 of the total maximum inertia and friction horsepower for carriage speeds of 150 and 360 feet per minute. The results are shown by Figure 14. These calculations assume no idle time for the carriage. It is important to note that the requirements of the drive may primarily be determined by the peak commutating ability of the motor and its associated generator. Machine rating of 150 per cent should not be exceeded and lesser values of overloading are to be preferred for this highly fluctuating load.

The generator is equipped with killer fields to prevent creep of the carriage with the controls in the "off" position and to assist in regenerative braking.

Nozzle Elevator Unit

It is necessary to adjust the nozzle for proper distance from the log for most effective barking. This may be done by hydraulic or air cylinders, self-locking lead screw, and motor mechanism on the carriage or by traveling cable arrangement to a stationary motor and drum unit apart from the carriage.

The first method presents no particular electrical problems. The others require special consideration as regards application of the motors. Ordinary polyphase

squirrel-cage induction motors have been found satisfactory, either normal torque or hoist type.

In the external cable drum and motor arrangement, Figures 3 and 15, from 8 to 15 operations per minute may be required for the fastest carriage drives having 18- to 24-inch nozzle length. The time interval that the motor runs is very short and little cooling is afforded by rotation to dissipate the heat resulting from the normally high inrush currents. It is considered good practice to overpower the motor to favor the heating problem. In most cases it is necessary to provide for forced air cooling of this motor.

An electric brake is provided on the motor shaft to hold the nozzle positioned when elevation adjustments are not re-required. The reversing controller and brake are interlocked for rapid release so that minimum duty is required of the motor. Figure 3 shows the cable arrangement by which the nozzle position on the moving carriage may be changed by the stationary motor and drum unit.

Barkerman's Control Desk and Cubicle

For maximum production it is essential that the barkerman's controls be designed to minimize both physical and mental fatigue. The variability of log sizes and their conditions greatly multiply the complexity and co-ordinated handling requirements with which he must continually deal. Figures 7 and 12 show one arrangement of control levers and handle operated push buttons by which this was effectively carried out. Arm movement of the levers is required only to make speed or operate selections which is comparatively infrequent. Reversing the carriage, changing nozzle elevation, unloading and loading and reverse rolling are all accomplished by the almost effortless action of depressing corresponding thumb buttons located at natural grip position on top of the control levers. The approach chains, also under the barkerman's direction are foot button operated.

In addition to the operating levers, the barkerman's desk is provided with push buttons and indicating lights for remote starting, stopping, and supervision of the following barkerhouse equipment which logically comes under his direction:

Operate foot button and lockout push-button for control of the fore-deck approach chains.

Main high-pressure water pumps.

Main motor generator set.

Main bark conveyor.

Hydraulic unloader pump motor (when used).

Barking lights.

Carriage backout reset, for use in case carriage overtravels the safety limit switches.

Alarm for wood mill superintendent and millwright.

Screen motors and auxiliary conveyors.

Figure 12 schematically represents the principal electric circuits and control apparatus. The detail control apparatus and devices which set up and perform the necessary functions as initiated by the barkerman are housed in a separate control cabinet, Figure 16.

High-speed nozzle carriage and log roll drives can be controlled economically in both speed and direction by Rototrol excitation for the generators. This arrangement provides a means of limiting the maximum current taken by the motors without regard to the rapidity with which the barkerman may manipulate his controls. A Rototrol controlled system is presently being manufactured in which the barkerman will control both the trunnion and carriage drives by means of a control wheel. The speed of trunnion rotation in either direction will be proportional to right or left hand rotation of the wheel from a central position. Similarly the nozzle carriage speed in each direction of travel will be proportional to the amount the wheel is moved forward or backward from its center or neutral position. The control wheel will be equipped also with finger tip control for raising and lowering the nozzle.

Conclusion

The Bellingham barker represents a distinct advance in round log hydraulic log barking machines. It is simple and versatile as related to the many handling requirements in large-size log debarking. The controls and drives all lend to simple and reliable solution by electrical circuits and apparatus. The success attained to date with this barker indicates that modifications in design and arrangement will be numerous to fit the additional requirements of the very small and very large log debarking.

It is expected also that the barker will find use in other industries and sections of the country as in mining for the barking of poles or mine timbers.

Appendix

Development of formulas for the production output of the Bellingham barker:

Let

R = surface speed of log in feet per minute
L = nozzle length in inches
D = mean diameter of log in inches
N = revolutions per minute of the log
E = barking efficiency
S = free running nozzle speed in feet per minute

Then

$R = \pi DN/12$

$S = NL/12$

$S = \frac{RL}{\pi D}$

Production in cubic feet per hour

$= \frac{RL\ 12}{\pi D\ 12} \times \frac{\pi D^2}{4(12)^2} \times E \times 60$

$= 0.104\ RLDE$

Production (solid cords per hour)

$\cong 0.00104 RLDE$

= Production in cubic feet per hour

$\frac{\pi D^2}{4(12)^2} \times SE \times 60$

$= 0.328\ D^2SE$

Modern Trends in Hydraulic Turbine Design

WM. J. RHEINGANS
NONMEMBER AIEE

Synopsis: Large welded plate steel spiral casings with plate thickness up to $2^3/_{16}$" for operation under heads up to 435 feet have been manufactured in recent years. On some casings both the shop joints and the field joints were welded without stress relieving by annealing. After three to five years operation there has not been a single case of a weld failure. Other intricate turbine parts such as coverplates, discharge rings, speed rings, Francis runners and impulse wheel buckets have also been fabricated out of welded plate steel. There has been an increase in the use of stainless steel to resist pitting, erosion and corrosion, resulting in reduced maintenance costs. Newly designed self-lubricating bearings and carbon ring seal rings have simplified operation and have eliminated sources of trouble and failure.

THE biggest advancements in the design of hydraulic turbines during the past ten years have been in connection with the materials of construction. There has been an increased use of welded plate steel in place of cast steel due partly to the lower cost of welded structures and the difficulty in obtaining sound castings. There has also been an increase in the use of stainless steel for the various turbine parts which are in contact with high velocity water. Self-lubricating bearings and carbon ring water seals are a distinct improvement in the design of the medium sized units, since they eliminate common sources of trouble.

Welded Plate Steel Construction

As the cost of patterns and steel castings kept increasing relatively faster during the past ten years than the cost of plate steel, it became more and more economical to use a fabricated construction. It has been very difficult also to obtain good, sound, steel castings in the sizes and shapes required for hydraulic turbines. Many of the castings received from the steel foundries have required nearly as much welding to repair cracks and defects as though it were a welded structure to start with. This has not only increased the cost of the castings still further, but has meant critical delays due to either major repairs or the replacement of castings that had to be scrapped.

Therefore when the four 103,000-horsepower 330 foot head turbines were purchased by the United States Bureau of Reclamation for the Shasta power plant in 1939, it was found that it would not only be economical but that it would be possible and practical to construct the spiral casings for these turbines out of welded plate steel rather than cast steel.

Shipping limitations, as to maximum dimensions, indicated that the casings be made up in seven sections. This meant that some type of field joint would have to be used. Several different methods were considered, including welding. However at that time very little information was available regarding the welding of such large structures in the field without stress relieving. Double butt strap riveted joints were therefore used for assembling the sections in the field.

Figure 1 illustrates the casings assembled in the manufacturing shops, and shows the welded shop joints as well as the riveted butt strap field joints. The inlet to the casing is 12 feet 8 inches in diameter, and the plate thicknesses vary from 1 to $2^3/_{16}$ inches. The finished weights of the seven sections, including the cast steel speed ring sections, varied from 26,000 to 58,000 pounds each. Figure 2 shows one of these sections, with the steel plates welded to the cast steel speed ring.

Handling of such large sections in the shops for economical and satisfactory welding procedure presented quite a problem. This was solved by the construction of tiltable welding tables, one of which is shown in Figure 3. This table is 20 feet in diameter and can be rotated through 360 degrees and tilted through an arc of 90 degrees. Figure 4 shows one of the sections of the casing mounted on the welding table for welding and grinding. These tables permitted the use of the Lindy Union melt method (a submerged arc type of welding process) for a large percentage of the joints and made it possible to do all hand welding, chipping and grinding in the position most convenient for the operator. Every welded joint

Paper 48-191, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 10, 1948; made available for printing July 16, 1948.

WM. J. RHEINGANS is with the hydraulic department of the Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

Figure 2 (left). One of seven sections of welded plate steel spiral casing for Shasta power plant turbines, showing plate steel welded to cast-steel speed ring

Figure 4 (right). One of seven sections of welded plate steel spiral casing for Shasta power plant turbines on tiltable welding table

was completely X rayed. Defects were chipped out and rewelded.

Because of the riveted field joint construction it was not practical to make a pressure test during erection in the shops. After assembly in the field each casing was tested to 310 pounds per square inch pressure which was double the normal maximum operating pressure. These tests developed no failure or leaks at any point in the casing, and five years of operation have indicated that the welded construction is entirely satisfactory.

The Shipshaw development on the Saguenay River in Canada was the first installation to utilize spiral casings of the all welded construction, where all field joints as well as shop joints were welded. This development consisted of 12 hydraulic turbines rated 100,000 horsepower each at 208 foot head. All of the plates in eight of the spiral casings were welded to each other and to the cast steel speed ring sections. The other four casings all used riveted joints.

Figure 5 shows the partial assembly of one of the welded casings in the shops. The welders are welding some of the plate joints comprising the sections as shipped. Figure 6 shows the assembly of one of the casings in the field before welding of the field joints.

The inlet diameter of each spiral casing is 16 feet, and the plate thickness varies from 7/8 to $1^3/_{16}$ inches. The casing was divided into 12 sections, the size of each section being determined by the maximum size that it was possible to ship. Each section consisted of a number of plates with longitudinal circumferential joints welded together in the shop. None of the plates were welded to the speed ring in the shop, making it possible to construct the speed ring in five sections instead of 11 which otherwise would have been necessary.

No stress relieving or annealing of the welded joints was done either in the shop or in the field. However all welding was done under extensometer and test bar control. The former controlled locked-up stresses and by proper peening, the necessity for stress relieving was eliminated. The test bar control consisted largely of impact tests of sections cut daily from the actual welds of every man. A general requirement of 30 foot pounds (Charpy) was demanded.

Deposited weight of weld rods ranged between one and two pounds per man per hour total elapsed time. The entire casing assembly and welding in the field ranged from two to four weeks and averaged about three.

The units were placed in operation during 1942 and 1943, and after five to six years operation no trouble of any kind has developed on the welded casings.

Another notable all welded spiral casing installation was made for the two 91,500 horsepower turbines for the Fontana development of the Tennessee Valley Authority. This installation is of particular interest because of the welded field joints in combination with a large casing under relatively high head. The gross head on the units varies from 435 feet maximum to 245 feet minimum with 330 feet as the rated head. The spiral casings have a 12 foot diameter inlet with plate thickness varying from $1^1/_8$ to $1^7/_8$ inches.

The speed ring was of cast steel and made up of five equal sections, designed to be rigidly bolted together. The spiral casing was divided into eight sections. Because of the relatively high operating pressures for this casing, it was decided to stress relieve all shop welded joints by annealing. Also, since the highest stress in the casing occurs near the joint between the plates and the speed ring, the sections were so designed that all of these joints were shop welded and therefore annealed. Each section consisted of a number of plates with circumferential joints.

Figure 3 (left). 20 feet diameter tiltable and rotatable welding table

Figure 5 (right). Partial shop assembly of all welded plate steel spiral casing for 100,000-horsepower 208 foot head turbine for Shipshaw Development, Canada

Figure 6. Field assembly of all welded plate steel spiral casing for turbine for Shipshaw Development, Canada

Figure 8. Shop assembly of all welded plate steel turbine parts for 50,000-horsepower, 195 foot head, turbine for Maraetai Plant, New Zealand

Field welding was done on both circumferential and longitudinal joints. All field welding was done under extensometer and test bar control. Each welding crew included a man who did nothing but peen the welds. The amount of peening was controlled by the extensometer readings, thus reducing the locked up stresses.

Tensile test bar specimens were cut daily from the actual welds of every man and tests were made immediately, on a portable tensile testing machine. As a further test of the strength of all the welded joints the casings were tested under 375 pounds pressure which is double the maximum static head on the unit.

Figure 7 shows one of the assembled Fontana casings in the shops. Field joints are clearly visible. The units have been in satisfactory operation since 1945.

In all of the casings described before, there has not been a single case of weld failure or even leakage either during the tests at excess pressures or during operation in the field. Since the welded joints in these spiral casings were all flush, the resulting benefit to smooth flow as compared to a riveted casing was reflected in exceptionally high turbine efficiencies as determined by actual field tests.

The completely satisfactory performance of welded casings under test and in field operation indicate the advisability of giving serious consideration to this type of construction for all future installations. In this connection it should not be overlooked that successful welding can only be obtained through proper design, application and control, based on a broad experience on the part of both the designers and the welders.

In addition to welded spiral casings, recent years have seen a trend towards welded construction of top plates, bottom plates, guide vanes, speed rings and shifting rings. An interesting example of this is the installation of the five 50,000 horsepower, 195 foot head turbines for Public Works of New Zealand, Maraetai plant. All of the principal turbine parts are of welded plate steel construction including the spiral casing, speed ring, top and bottom covers, guide vanes, shifting ring, draft tube liner and pit liner. Figure 8 shows the shop assembly of one of these units and Figure 9 the all welded discharge rings. Figure 10 shows one-half of the all-welded coverplates. The two halves will be rigidly bolted together. This was the most complicated welded structure in the entire turbine. Figure 11 shows the completely fabricated and welded speed ring (in halves) on skids prior to ship-

ment. The pipe braces are used to prevent deformation in transit. The spiral casings will be of all welded construction without stress relieving by annealing. These units have not yet been placed in operation.

Where a sufficient number of duplicate runners are desired so that the die cost per runner is not too great, all welded Francis runners can be built. Up to the present this type of construction has been confined to runners for the lower heads (below 100 feet) because of the varying blade thickness required for the higher heads. Figure 12 shows a Francis runner with die-formed plate steel buckets welded into a cast steel crown and rolled steel discharge band. This is one of 18 replacement runners for the three horizontal sextuplex units of the Wisconsin Power and Light Company, Kilbourn plant, operating under 30 feet head.

This type of construction has several advantages. It produces very smooth runner bucket surfaces; water passages that are true to the desired shape; and uniform discharge openings, all of which tend towards high efficiency and smooth operation.

Fabricated housings for large butterfly valves for use as penstock shut-off valves have also seen increased use in recent years. Figure 13 shows a 15 foot diameter butterfly valve with an all welded plate steel housing, for the Grand River Dam power plant for operation under 115 feet head. The valve wicket is of cast steel. The housing was split to facilitate handling and field erection.

One of the most recent applications of fabricated structures is in connection with impulse wheel buckets. Considerable trouble has been experienced in recent years trying to obtain sound bucket castings. Because of the high water velocities it is imperative that the bucket bowl surfaces be highly polished and absolutely free of pin holes or defects of any kind. This strict requirement results in the rejection of a large percentage of bucket castings and requires considerable repair work and grinding on acceptable castings. By forming the bucket bowls out of plate steel all of these difficulties are eliminated. Figure 14 shows two of 52 fabricated buckets being manufactured for the Southern California Edison Company. The bucket bowls are of pressed plate steel. The splitters are forged steel and are welded to the bucket bowl. The lugs are of plate steel 4 inches thick and are welded to the back of the bucket. These buckets will be installed in the Big Creek 2-A unit rated 56,000 horsepower, 2,200 feet head.

Buckets similarly fabricated were installed in 1944 in a Southern California

Edison Company, Big Creek plant number 1, unit rated 22,500 horsepower at 1,900 feet head. They have now given four years of satisfactory operation without showing any signs of failure or wear.

Use of Stainless Steel

In addition to the increased use of fabricated plate steel in hydraulic turbine construction, the tendency towards use of stainless steel is increasing very rapidly. Stainless steel has the property not only of resisting the pitting action due to cavitation, but resists corrosive action due to chemicals in the water and resists erosive action of high velocity water which contains solids, such as sand, grit or glacial silt.

The use of stainless steels to resist pitting dates as far back as 1928. This has been mostly in the form of welded stainless steel overlays on mild cast steel surfaces at points where it was anticipated that pitting would occur. A recent innovation has been the use of stainless steel strips welded to the surfaces, see Figure 15.

This latter method not only decreases the cost of surfacing with stainless steel, but insures a more uniform thickness of the overlay and acts as a guide to the true runner bucket shape during grinding and finishing operations.

During the past few years a number of all cast stainless steel runners have been manufactured. Figure 16 shows a 20,000 pound cast stainless steel runner for the Brazos power plant, Texas. The original cast steel runners for this plant wore very rapidly due to excessive corrosion. Repairs with stainless steel on these runners indicated that stainless steel would have a high resistance to the corrosive action. Since the corrosive action was not confined to small areas but affected the entire runner, the use of a solid stainless steel casting was justified.

Solid stainless steel runners have also been successfully used where other materials were subject to considerable erosive action due to sand or grit in the water.

Use of stainless steel on hydraulic turbine parts have proved to be beneficial when used in connection with guide vanes, facing plates above and below the guide vanes, wearing rings both stationary and on the runner, discharge rings, and shaft sleeves for the main shaft where it passes through a stuffing box.

Stainless steel needles for impulse wheels have given years of very satisfactory service in many instances where mild steel or bronze needles eroded after a short period of operation. The use of stainless steel for valve seats for butterfly valves, pressure regulators and similar applications has been very successful in eliminating wear due to leakage.

Francis turbines for heads above 700 feet are subject to considerable wear due to both cavitation and erosion, aggravated by high velocity of flow. Some of the recent high head installations are therefore using stainless steel for all turbine parts which come in contact with high velocities. This includes the guide vanes, facing plates, runners, wearing rings and discharge ring. It is believed that this will largely eliminate or reduce the wear generally encountered with high head installations. If operating experience shows that stainless steel meets the expectations of the designers, reaction turbines can then be used for heads which had previously been considered impractical.

Figure 20. Test of 18½ inch diameter carbon ring water seal showing leakage under 20 pounds pressure

Self-Lubricating Bearings and Carbon Ring Seal Rings

Other trends in the design of hydraulic turbines are noted in improved bearing designs and seal rings. Figure 17 shows the location of these new designs on a vertical shaft Francis turbine.

With reference to the main bearing, hydraulic turbine designers have borrowed the self-lubricating bearing with appropriate modifications which has been used successfully on hydrogenerators for many years. Figure 18 shows an outline of this type of bearing. The bearing runs in an oil bath covering about one-third of its vertical length. The babbitt in the bearing has longitudinal grooves so slanted that the rotation of the shaft produces a pumping action. Oil is thus forced from the oil reservoir to the top of the bearing where it floods the entire upper portion of the bearing. In addition the grooves are so shaped that the shaft will pick up oil from them and carry it around to the remainder of the bearing surfaces.

The main feature of this bearing which makes its use possible is a leak proof oil reservoir. This means that the shaft has to be hollowed out longitudinally as shown in Figure 18, in order to permit installation of an oil reservoir which does not have to depend upon a stuffing box or packing box around the shaft to hold the oil.

This type of construction means that the actual bearing diameter is considerably larger than the rest of the shaft diameter, and therefore the use of the self-lubricating bearing has been confined to shafts of 20 inches or less diameter.

However the simplicity of the lubrication, the elimination of all mechanical means for circulating the oil and the economical type of construction have caused it to be very much in demand for the smaller size units. In addition to the large number of self-lubricating bearings of this type in operation on hydrogenerators, one has been in operation on the 12,500-horsepower 230 foot head turbine for Puente Grand power plant, Mexico for five years, and so far has given entirely satisfactory service.

The type of stuffing box, or packing box commonly used where the shaft passes through the top cover, has not been too satisfactory. It requires constant adjustment, because if it is too tight, it heats up and scores the shaft, and if it is too loose, the leakage becomes too great. It produces sufficient wear on the shaft so that renewable sleeves usually of stainless steel are installed at this point.

Figure 19 shows a carbon seal ring which can replace the stuffing box. This seal consists of two split carbon rings held against the shaft by means of garter springs. The two rings are separated by a spacer. Water and grease lubrication are provided, although the rings should operate for long periods of time without any lubricant, and without heating.

Tests were made on a seal ring of this type for an 18½ inch diameter shaft. The leakage through the seal at 20 pounds pressure was about a quart of water per minute.

Figure 20 shows the test setup.

The advantages of the carbon seal ring are that it requires no adjustment or attention, does not require renewal, and should produce very little wear on the shaft. Therefore it can be used in places which would ordinarily be inaccessible or which would require special design and construction to make the packing ring easily accessible for adjustment. There is a good possibility that the carbon seal ring will cause so little wear on the shaft that the usual stainless steel sleeve can be eliminated. Seal rings using lignum vitae blocks instead of carbon, have been in operation for over ten years and have been entirely satisfactory. Carbon seal rings have not as yet been in service on hydraulic turbines, but based on their performance on steam turbines under high temperatures and pressures, and based on laboratory tests, it is predicted that they will be entirely satisfactory.

Conclusion

In conclusion it can be stated that the general trend in turbine design is towards the better and more economical use of available materials as characterized by the increased use of welded plate steel structures. The increased use of stainless steel and the new types of bearings and seal rings indicate the desire of the designers to reduce field maintenance as much as possible, with a resulting reduction of costly outages.

No Discussion

Telemetering Circuits—Metallic and Carrier

M. A. BOSTWICK
MEMBER AIEE

TELEMETERING is an art that has enjoyed a steady development for 30 years. In its beginning it consisted simply of measuring an electrical quantity at one point and transmitting it over metallic circuits to a remote point for indication. It saved many steps and telephone calls by placing continuous indications of magnitude of current, voltage, and power in front of the power station operating engineer. From this simple beginning it has expanded to encompass entire power systems and interconnections to adjoining power systems. The data that are gathered in this manner are so accurate and the methods that are used to totalize that information are so reliable that the telemetering equipment and the associated automatic load control apparatus are now performing many functions that directly aid the power system dispatcher himself. The value of such telemetering systems and automatic load control have been amply demonstrated in many installations.[1–4] Recent developments in telemetering systems have been described also in several papers.[5–8]

Typical telemetering systems are illustrated by block diagrams, Figures 1 and 2. Figure 1 illustrates the measurement, transmission, and recording of power and reactive voltamperes throughout a power system. The information is placed in front of the load dispatcher to guide him in controlling operation of the power system. Figure 2 illustrates an expansion of the system to include automatic load control and thus relieve the dispatcher of routine work. This automatic control provides increased operating efficiency as described in references.[1–4]

This paper is written to provide a review of the art of telemetering, with special emphasis on the circuits that are used to transmit the information from the points of measurement to the points of utilization. The paper includes brief descriptions of the general types of telemetering apparatus that are now in use; a description of metallic, carrier frequency and radio frequency circuits that are used for transmission of the information, and a look into the desirable future. The paper also indicates limitations of the various circuits, and provides a guide for future planning of the economic use of telemetering equipment.

To provide a clear picture of the telemetering problem, it is desirable to classify the many different types of telemetering systems that are available. All telemetering apparatus that is now on the market can be divided into the following general types: voltage; current; and impulse.

The different circuits that are used to transmit the metered quantities can be classified as metallic, carrier frequency, and radio frequency.

It is proposed to discuss the various types of telemetering briefly so as to obtain a common ground for discussion. The various telemetering circuits will then be described. This description will include a discussion of circuit requirements and limitations. Finally the various types of telemetering apparatus and circuits will be discussed in combination with carrier relay and communication circuits to provide dependable and economic solutions to the telemetering problem.

General Types of Telemetering Systems

Voltage Types

Telemetering transmitters which employ voltage magnitude as a means to transmit intelligence include; thermal converters, slide wire position indicators, and polyphase wound rotor motors. The thermal converter employs a polyphase ($E+I$ and $E-I$) heating element to energize thermocouples so as to produce millivolts proportional to watts or reactive-volt amperes. Similar thermal converters are made to provide millivolts proportional to voltage squared or current squared. Limited amounts of energy can be drawn from these devices to actuate indicating or recording instruments. Potentiometer-type recorders which draw no energy from the measuring device are usually used. A metallic circuit that is well insulated and free from disturbing voltages must link the thermal converter with its associated recorder.

A retransmitting slide wire is frequently built into the recorder to provide a means of totalizing recorded quantities. This slide wire may be operated from alternating current when totalization is performed with instruments on the same panel.

Retransmission of the recorded quantity over an appreciable distance requires use of a d-c slide wire, or the use of impulse telemetering. Slide-wire potentiometers can be used in a similar manner to transmit appreciable amounts of energy to a remote point to actuate indicating instruments directly. This is done to indicate the mechanical position of some device, as a water level indicator, a tap changing regulator and so forth.

Servomechanisms are used in a similar manner to indicate position at a remote point. Motor operated devices of this kind require a 3-wire circuit and voltage references that are in phase at each terminal. Large boiler room indicators that are operated from a recorder in the

Paper 48-194, recommended by the AIEE joint subcommittee on telemetering and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 10, 1948; made available for printing July 19, 1948.

M. A. Bostwick is with the Westinghouse Electric Corporation, Newark, N. J.

Figure 1. Block diagram of telemetering circuits using metallic and carrier circuits

Figure 2. Circuit additions to Figure 1 for load control

same power plant are an example of this type of telemetering.

Current Types

Current operated telemetering devices generally differ from the voltage operated devices in the magnitude of energy that is used to transmit the intelligence. The voltage operated devices, more especially the thermal converter and retransmitting slide wire, operate with millivolts. Practically no energy is transmitted. The current operated device controls the transmission of considerable amounts of energy which can actuate the receiving indicator or recorder directly. Special means are used to control the transmission of current without affecting the accuracy of the primary measuring element. These means include the current balance transmitter which balances the magnitude of current that is sent to a remote indicator against the torque of the primary measuring element. This balance is usually obtained indirectly through the aid of sensitive platform balances, or by the use of photo cell devices that will not affect the accuracy of the primary measuring element. The transmitter voltage that is used in these circuits is in the order of 50 to 100 volts. This makes the current balance transmitter less sensitive to voltage disturbances or leakage that may be encountered in relatively long metallic circuits.

Impulse Types

Impulse telemetering as described in this paper includes: transmitters that operate at a rate that is proportional to the metered quantity, transmitters that operate at a fixed rate with an impulse duration that is proportional to the metered quantity, and frequency transmitters which are for the purpose of this discussion impulse rate transmitters.

The problems that are encountered in transmitting signals for these systems are all characterized by the impulse rate and impulse duration systems. Since these telemetering systems employ a rate or duration of signal to transmit intelligence, practically independent of the magnitude of the transmitted signal, they are well suited to control of carrier or space radio circuits. They are similarly relatively free from errors that might be introduced by extraneous voltages in metallic circuits.

Interconnecting Circuits

Metallic Circuits

The maximum length of metallic circuits that can be used between the transmitters and recorders that have been described is usually determined by economic factors. Thermal converters, retransmitting slide wires, or a number of these devices connected in series for totalization are usually operated over metallic circuits of less than five miles in length. However, installations are now in service, operating over typical telephone circuits where the distance between transmitter and receiver is as great as 25 to 30 miles. Disturbing voltages, that appear between wires, or leakage in the form of direct current passed through wet cables or across dirty terminals, cannot be tolerated in circuits of this kind. Twisted pairs of wires, in cable maintained in accordance with telephone practice for full metallic ungrounded circuits, are required.

Current operated transmitters are capable of being operated over circuits of greater length. However, the current type finds its principal application in circuits that are not equal to telephone quality (in this paper "telephone quality"

Figure 3. Network circuit for telemetering two quantities over one metallic pair

requires that leakage resistance between wires, or from wire to ground, shall exceed 50,000 ohms). The relatively high level of voltage that is used in current operated telemetering circuits permits greater voltage disturbance in the metallic circuit. Automatic telemetering controls that hold the circulating current to a correct magnitude also tend to limit the effect of disturbing voltages. Current operated transmitters can also be used to operate several receivers connected in series.

Impulse telemetering is generally less sensitive to the introduction of extraneous voltages in the metallic circuit than either the current or voltage types of telemetering. The interfering voltage between wires must be large enough to operate the impulse receiver to affect the accuracy of telemetering. Momentary pulses of disturbing voltage will have practically no effect on the received signal as the indication or record is proportional to the rate or duration of the received impulse. Impulse telemetering also has the advantage of being able to utilize phantom, simplexed, and network circuits. Either direct or alternating current can be used. These circuits permit the simultaneous transmission of two or more signals over a given pair of wires. An example of the network circuit is shown in Figure 3.

The foregoing considerations are summarized in Table I.

Protection of Metallic Telemetering Circuits

Metallic telemetering circuits should be studied to make certain that adequate protective devices are installed. This is required to avoid injury to operating personnel and damage to equipment. Leased telephone circuits usually include the necessary protective features. However, the protection is primarily designed for telephone circuits and may not be adequate to prevent damage to sensitive terminal apparatus. This is particularly true when disturbing voltages are of a magnitude that will operate only one protector block so as to apply an extraneous potential between wires. Generally the protection will consist of 350-volt carbon blocks and 0.35 ampere fuses. These will be supplemented by neutralizing transformers, if disturbing voltages in excess of 350 volts are likely to be impressed on the leased circuit.

The general problem of protecting metallic circuits has been previously discussed.[9,10] The first of these papers describes the manner in which disturbing voltages are impressed on the metallic circuit and illustrates use of a two winding neutralizing transformer. The second paper[10] describes use of a mutual drainage reactor for protection of low-voltage metallic circuits. The neutralizing transformer is particularly well adapted to the protection of open pilot circuits that have a relatively high level of insulation. It is rated at 4,000 volts, and operates to distribute the voltage stress in the form of IZ drops across the windings of neutralizing transformer itself. The mutual drainage reactor is particularly valuable for the protection of low-voltage a-c circuits. It operates to distribute the voltage stress by IZ drops in the metallic circuit itself. The reactor has sufficient impedance (between wires) to avoid interruption of many a-c circuits, even when it is actively "draining" extraneous voltages from the interconnecting circuit.

Audio Frequency Tone Channels on Metallic Circuits

As many as ten audio frequency tone transmitters and receivers are available for simultaneous transmission of telemetering signals over a pair of wires. Impulse telemetering must of course be used. This installation of carrier and audio frequency tone transmitting equipment is illustrated in Figure 1. As shown, it includes practically all types of carrier and metallic telemetering circuits. Installations of this kind must of course be co-ordinated with telephone circuit requirements.

Carrier Circuits for Telemetering

Carrier telemetering circuits, as discussed in this paper, refer primarily to power line carrier channels. They include:

1. Single frequency telemetering circuits.
2. Combined relay and telemetering circuits.
3. Audio frequency tone modulated telemetering circuits.
4. Amplitude modulated carrier circuits for combined communication, telemetering and protective relay control.
5. Single side-band telemetering circuits.
6. Combined single side-band telemetering and communication circuits.
7. Single side-band circuits for communication, telemetering and protective relay control.

In the following discussion reference will be made to typical amplitude modulated and single side band carrier equipment. All components of this equipment are assembled on standard 19 inch panels for easy inspection. New units can be readily added as service requires new features. The units include all elements that are required to assemble many different combinations of equipment. These units include: transmitters, double receivers for relay control and communication, superheterodyne receivers, audio frequency tone transmitters, tone receivers, hybrid units for 2-wire telephone extensions, code bell calling units, selective ringing units,

Table I. Summary of Metallic Circuit Requirements

Type of Telemetering Transmitter	Magnitude of Signal Impressed on Metallic Circuit: Voltage	Magnitude of Signal Impressed on Metallic Circuit: Current	Type of Signal That Carries Intelligence	Metallic Circuit Required	Number of Signals per Pair of Wires
1. Thermal converter	50 millivolts	0	Voltage magnitude	Highly insulated twisted pair with no appreciable leakage	1
2. Slide-wire retransmitter	1 volt	0	Voltage magnitude	Highly insulated twisted pair with no appreciable leakage	1
3. Slide-wire position indicator	125 volts	As required	Voltage magnitude	Dependent upon accuracy required	
4. *Servo-mechanisms	75 volts	0-550 milliamperes	Voltage magnitude	3-wire 100 ohms per wire	1
5. Current balance transmitter	125 volts	Milliamperes as required	Current magnitude	Substantial pair not necessarily twisted	1
6. Impulse telemetering	125 volts	Milliamperes as required	Impulse rate. Impulse duration	Substantial pair not necessarily twisted	—2 (See Figure 3)

Figure 5. Single side band carrier telemetering and load control circuits

single side band auxiliaries, d-c controls and rectifiers for a-c operation.[11]

1. Single frequency telemetering circuits require one transmitter and one receiver for each quantity transmitted. The carrier equipment can be of the standard relay design which requires a channel width of approximately 2 kc (when sharply tuned) or of the crystal controlled narrow-band type that requires only a few hundred cycles of the carrier frequency spectrum. The relay type of transmitter has the advantage of being standard equipment for use in protective relay control circuits. It can be modified also by the addition of tone transmitters to make it suitable for transmission of as many as ten telemetering signals simultaneously over one carrier channel. It is readily adjusted to operate at any frequency in the chosen frequency band.

2. One quantity can be telemetered over a protective relay carrier circuit, simply by keying the carrier transmitter and adding auxiliary equipment to prevent ringing carrier alarms by the telemetering impulses. Time delay features are usually added to control ringing from either line terminal for emergency communication. Protective relay action supersedes all other functions for the duration of transmission line faults. Telemetering must be interrupted when the circuit is used for communication. Circuits of this kind are used primarily for branch circuits, to transmit a single measurement into a trunk line. The impulse signal is repeated by auxiliary relay action. The relay receiver that is used in telemetering circuits of this kind is capable of operating through a carrier frequency loss of 30 to 33 decibels.

3. The single frequency telemetering circuit described in the foregoing paragraph 1, can be expanded by the addition of audio frequency tone transmitters and receivers to make it suitable for trunk line operation. As many as ten audio frequency tones can be keyed simultaneously to transmit ten quantities to a remote point. With such a circuit a channel width of approximately 6 kc is required. The signals can be received on the tuned-radio-frequency receiver, (the broad band receiver of a relay set) which is capable of being operated through 50–53 decibels. A superheterodyne receiver which is available also for use on telemetering and communication circuits, is capable of operating through 80 decibels. Tone transmitters and receivers must, of course, be added for each telemetered signal.

4. Protective relay circuits are readily expanded to provide continuous telemetering of four quantities with simultaneous point-to-point communication. High pass filters are provided to effectively separate telemetering and communication circuits. Double frequency carrier operation is required to permit conversation in each direction without interrupting the telemetering channel. All operation must be superseded by relay action momentarily during power system faults.

To assure high speed clearing of faults, when the line is reenergized from the telemetering receiving terminal, a circuit is required to interrupt the telemetering transmitter. This function can be performed in one of two ways.

A. Voltage fault detectors connected to line potential transformers can be used to stop carrier on loss of voltage.

B. A double frequency circuit can be used. For example as shown in Figure 4, frequency 1 is used for telemetering and communication from terminal *A* to terminal *B*. Frequency 2 is used in the reverse direction. Each relay-type receiver includes two units, a narrow band saturated single tube receiver for relay control and a broad band TRF receiver with automatic volume control for reception of voice and telemetering signals. The voice receivers are set to receive telemetering frequencies as described before. The relay receivers are set to receive the "inverse" frequency. The protective relay control circuits are adjusted to initiate transmission of frequency 2 from terminal *A* and frequency 1 from terminal *B*. High-speed relay action is thus assured under all operating conditions. The relay receivers cannot be blocked by reception of a telemetered signal as they operate on different frequencies. The essential feature is, that a carrier blocking signal cannot be transmitted by the communication or telemetering circuit. Consequently high-speed carrier relay protection is assured

even at a time when fault current is not transmitted through one line terminal in sufficient magnitude to operate protective relays.

Since relay controls are independent of communication and telemetering circuits, automatic dialing and all forms of communication auxiliaries can be used. Extensions of the communication or telemetering circuit beyond the line terminals must be made by audio frequency by-pass circuits. When two or three audio frequency by-passes are used for communication circuits, the audio frequency response is maintained essentially flat from 100 to 3,000 cycles by addition of equalizing amplifiers. If only a few audio frequency tones are to be transmitted on through adjoining carrier channels, audio frequency tone amplifiers can be installed to receive, filter, and amplify each tone. The output of the tone amplifier can then be used to modulate the next carrier transmitter.

In this manner tones can be repeated through a number of line sections. As previously stated one audio frequency by-pass can be made around a line terminal without use of auxiliary equipment. Each additional by-pass circuit requires tone amplifiers for telemetering tones, or an equalizer and amplifier to repeat the entire audio spectrum.

Directional comparison carrier relay controls can be operated through the higher frequency tone channels if desired. Circuits of this kind have the advantage of permitting telemetering circuits to be operated continuously, without interruption for protective relay control.

5. Single side-band carrier channels are highly selective and are particularly well suited to transmission over long distances. As pointed out in previous papers,[12,13] all of the carrier energy is available for transmission of the desired signal. The single side band carrier circuit uses extremely accurate frequency controls. It inherently provides a carrier receiver that is capable of receiving ten signals simultaneously, from widely separated points in the power system using only one carrier frequency. These signals may include a number of tone modulated signals that are transmitted from a given point, and single quantities transmitted from different points. A circuit of this kind is illustrated in Figure 5. As indicated in the block diagram, audio frequency tone transmitters are required only at locations where more than one quantity is to be transmitted. The single side band transmitter itself, can be tuned to transmit the equivalent of one tone modulated single side-band signal, either 100.15, 100.209, 100.403, 100.29, 100.56, 100.778, 101.08, 101.5, 102.08, or 102.9 kc for example. These tone modulated signals can be received as separate and distinct tones by tone receivers operating with one single side-band receiver.

Load control signals can be broadcast from the dispatcher's office by a second carrier frequency. In this manner it may be possible to establish an entire telemetering system with two carrier frequencies.

6. The features described in paragraph 5 can be obtained in combination with two frequency communication circuits. However, in this case, the number of quantities that can be telemetered is limited to five in each direction using 150, 209, 290, 403, and 2,900 cycle tones separated from the voice circuit by suitable filters. This leaves a frequency band from 500 to 2,500 cycles, which is adequate for clear, intelligible speech. If the 2,900-cycle tone is not required for relay or telemetering control, the speech channel will include frequencies from 500 to 3,000 cycles per second.

7. The single side band carrier equipment can be used in a similar manner for communication, telemetering, and protective relay control. As previously indicated, the protective relay circuit will employ the 2,900-cycle tone channel, speech and telemetering circuits will use frequencies mentioned before.

A summary of these considerations is given in Table II.

Radio Frequency

The use of microwave radio for transmission of telemetering, communication, and protective relay control signals presents many interesting possibilities. Frequencies in the order of 952 to 960 megacycles are being used experimentally for this purpose. Investigations indicate that space radio can provide reliable circuits for multiple uses. The signals are essentially transmitted through a line of sight. A narrow beam of microwave energy approximately 20 degrees wide

Table II. Summary of Available Carrier Frequency Telemetering Circuits

Type of Carrier Equipment	Number of Telemetering Circuits	Number of Carrier Frequencies Required	Auxiliary Functions: Communication	Auxiliary Functions: Protective Relaying	Auxiliary Functions: Supervisory Control	Auxiliary Functions: Load Control	Permissible Carrier Attenuation
Single transmitter and receiver (relay type)	1	1	*	*	*	*	30-33 db+
Crystal controlled	1	1	–	–	–	–	80 db+
Relay transmitter and receiver	1	1	1	1	1	*	30-33 db
Single transmitter with superheterodyne receiver	1	1	*	*	*	*	80 db
Tone modulated transmitter with relay receiver and high pass filters	4	2	1	1	*	*	30-33 db relay channel 50-53 db audio channel
Tone modulated transmitter with superheterodyne receiver	10	1	*	*	*	*	80 db
Tone modulated transmitter with superheterodyne receiver, high and low pass filters	1	2	1	1	1	2	80 db
Single side band telemetering transmitter and superheterodyne receiver with tone filter	1	1	*	*	*	*	90+ db
Single side band tone modulated telemetering transmitter with superheterodyne *SSB* receiver	10	1	–	–	–	–	90+ db
Single side band tone modulated carrier telemetering, relaying and communication with superheterodyne *SSB* receiver	4	2	1	1	*	*	90+ db

* Indicates functions that can be added.

will be transmitted. These considerations, and local obstructions will fix the height of towers and distances between towers. Two antennas are required at each terminal for double frequency operation. Each radio channel should be capable of transmitting a large number of signals simultaneously, in addition to providing communication circuits. Consequently it is to be expected that equipment of this kind will be suitable for the transmission of many signals between locations that cannot be economically served by other means.

Circuit Combinations

As indicated in Figures 1 and 2 it is expected that different types of telemetering measuring devices and transmitters will be used in assembling power system measurements at the power system dispatcher's office. Single measurements, that are made within Metropolitan areas, can be most easily made and transmitted to the dispatcher's office by use of thermal converters, telephone cable circuits, and potentiometer recorders.

At greater distances from the dispatcher's office measurements of a number of circuits at one location can be most readily totalized by use of multielement watt meters. These meters are arranged with photoelectric controls to transmit impulses proportional to the measured quantity. The impulses can be transmitted either by metallic circuits or via carrier circuits to the dispatcher's office. Impulses can be repeated by addition of auxiliary relays at pilot wire terminals to control carrier transmitters. Polyphase measurements can also be totalized by use of a number of thermal converters at one location. The sum of these voltages can be used to control a potentiometer recorder with impulse duration transmitters, which in turn control impulse transmission to the dispatcher's office.

In some power systems, it will be found most economical to use protective relay and communication circuits for the transmission of impulses to control locations. At these points the impulses can be repeated by audio frequency bypass circuits or mechanical means to control multitone transmitters on main line circuits. In other systems the use of narrow band transmitters, sending impulses direct to multi-circuit receivers as shown in Figure 5 will be preferred. Each application must be studied as an individual problem to determine the best solution.

Totalization

Information that is transmitted to the dispatcher's office, in the form of impulses, is usually recorded as measured to indicate power flow throughout the system. These quantities are then totalized through action of slide-wire attachments on the individual recorders. Alternating-current slide wires are used for totalization when all instruments are located on one switchboard. Direct-current slide wires are used when the recorders are more widely separated. The speed of totalization is dependent upon operation of mechanical recording devices. Because of this, it is desirable to totalize quantities electrically wherever such totalization can be obtained without omitting desirable records.

Impulse receivers can be connected in series to provide this totalization. Indicating instruments can be operated from each impulse receiver that is used in a totalizing circuit. However, the totalization must be performed through retransmitting slide wires when potentiometer recorders are controlled from impulse receivers. This is required to avoid interaction between recorder and impulse receiver circuits. These considerations indicate desirable features for future development. Totalization should be performed electrically wherever possible to avoid needless delay in mechanical circuits. It is essential also to perform that totalization in a manner that will not introduce undesirable time delay in the electrical circuits.

Recent developments in transmitters[6,7,8] have substituted electronic devices for mechanical features to obtain increased accuracy and speed of telemetering. Further developments in totalizing means are to be expected.

Conclusion

The art of telemetering is gaining in importance as its use is extended in the field of power system control. Increased numbers of power system interconnections have added to the number and complexity of system dispatcher's duties. The additional sources of information and automatic controls that can be gained by telemetering not only aid the dispatcher, but enable him to obtain increased operating efficiency of the entire power system. These desirable ends can be gained most easily by studying the various types of telemetering equipment and the transmitting circuits that are available and using equipments that are best suited to the application.

The crowding of carrier channels and the desire to obtain maximum use of equipment dictate increased consideration of circuit combinations that have been discussed in this paper. The single side-band carrier circuits are of particular interest since they offer the double features of carrier frequency conservation and added sensitivity.

Discussion

H. C. Thomas and **E. E. Lynch** (General Electric Company, West Lynn, Mass.): The classification of telemetering systems given by the author is abbreviated as compared with the accepted AIEE standard definitions of types, and the reasons for his deviation are not apparent. In fact, since the paper is written with special emphasis on the circuits that are used to transmit the information from the points of measurement to the points of utilization, it would appear important to classify the telemetering systems from this point of view.

The most serious consequence of the abbreviated classification which the author uses is in connection with impulse telemeters. In this classification is included telemetering systems which employ, as translating means, impulse-rate, impulse-duration, and frequency. Each of these translating means may call for transmission

circuits having different characteristics.

In the case of impulse-duration systems, it is usually important that the wave-shape of the transmitted signal be faithfully preserved. Thus, it is important to select transmission circuits having a relative wide band frequency response. This requirement is often not present in impulse rate systems, where the wave-shape of the signal at the receiver end of the telemeter channel may be of less importance.

Frequency-type telemetering systems are distinguished from impulse-rate systems in that the electric signal used for transmission is continuous, rather than intermittent, that is, usually a sine wave. This is an important difference from the point of view of the transmission circuit. The continuous signal can be designed to have a minimum harmonic content, whereas the intermittent signal is rich in harmonics. The presence of harmonics in the transmitted signal subjects the telemetering system to the possibility at least of serious interference. This is especially true in carrier-current transmission systems wherein several telemeter signals are superimposed on a single carrier signal, using audio tones and double modulation. Thus, in frequency-type telemetering systems, selectivity requirements of the transmission channel are minimized.

G. M. Thynell (The Bristol Company, Waterbury, Conn.): The valuable data contained in Bostwick's paper would have been more informative if he had recognized the standard classification of telemetering systems given in the "Definitions of Electrical Terms"[1] and adopted in the AIEE reports on the subject. The author's statement to the effect that, "All telemetering apparatus that is now on the market can be divided into the following general types: voltage, current, and impulse," according to the above mentioned standards is incorrect. Frequency-type systems have been completely ignored, and position-type systems have been confused with voltage-type systems, as indicated by the inclusion of servo-mechanisms under the heading of Voltage Types.

Telemetering systems of the frequency type are commercially available in at least four distinct forms; and those of the position type from at least eight different sources. Among the latter may be mentioned the author's own company which offers the "Synchro-tie" as in the position class of telemetering. The author, on the other hand, has classified this system as of the voltage type. While the several types of carrier equipment listed and discussed under the heading, Carrier Circuits for Telemetering, include only those manufactured by the author's company, no such qualifying statement appears in the text; and without such a limitation the classification is manifestly incomplete. A similar comment may be directed to such statements as "All components of this equipment are assembled on standard 19-inch panels. . . . . ". While this is doubtless true for the apparatus which the author had in mind, it does not necessarily hold for corresponding equipment obtained from other sources.

G. S. Lunge (General Electric Company, Schenectady, N. Y.): Under the head of Totalization, the author states that "recent developments in transmitters have substituted electronic devices for mechanical features to obtain increased accuracy and speed of telemetering." This statement refers only to transmitter changes, whereas two of the systems employed improved receivers.

Without an improved receiver, it is difficult to understand how either the accuracy or the speed of response of the telemeter system could be increased as compared with earlier designs, bearing in mind that the very high damping required in the receiver was the principal source of slow response. The author's statement was presumably intended to apply to reference 5.* The other two references (6 and 7) describe telemeter systems that include electronic receivers that are free from moving parts and hence permit the use of sufficiently high signal (keying or modulating) frequencies to make it possible to dispense with high damping in the receiver circuits or in the end device (indicating or recording instrument). Only the system mentioned in reference 7 takes full advantage of this possibility; the over-all response time of the system described in reference 6 is stated as 20 seconds, including the time of response of the end device (recorder).

* See author's references.

E. W. Kenefake (General Electric Company, Syracuse, N. Y.): Telemetering circuits are of general interest to the power industry due to the increased use of telemetering in the normal operation of a power system and this paper is a timely presentation. However, it would have been worth-while to have amplified certain data and application information presented in this paper.

In discussing the operating range of various types of equipment, the author points out that the operating range, depending upon the receiver used, may be 30–33, 50–53, or 80 decibels. Also, in Table II, the author mentions a rating of 90+ decibels for the single side band equipment. Is it proper to assume that these ranges are laboratory operating ranges, indicating the ultimate capabilities of the equipment, when no line noise exists? This question arises, because in a practical application on a power line involving line noise, the available operating range of a given type of channel cannot be extended merely by the use of a more sensitive receiver. To preserve the same signal-to-noise ratio this must be accomplished by increased transmitter power or by narrowing the band width. If the receiver selectivity is already as narrow as the channel will permit, then only transmitter power can be increased to improve signal-to-noise.

It is evident that the practical application of equipment to a power line must involve some estimate of line noise to evaluate what transmitter power is needed. To this end the author should indicate what transmitter power he recommends for the various operating ranges. In many applications the problem of interference caused by the use of high transmitter power will more than offset the advantages of the increased range obtained with the high power.

It is indicated that the operating ranges given in the paper apply to the transmission of tones. If one tone fully modulates the transmitter then all the sideband energy is devoted to one tone. However, when several tones modulate a transmitter, the per cent modulation that can be devoted to each tone is lessened by the number of tones transmitted. This sharply reduces the transmitted power associated with each tone. If we assume these ranges apply when the full capability of the transmitter is used for a single tone, this rating must be reduced as additional tones are added; since the equivalent power for each tone must reduce as $1/n^2$ where n is the number of tones. This would be a 20 decibel reduction in operating range when ten tones are used.

In addition, it would have been worthwhile for the author to have devoted more of his paper to the proposed use of four tones below the voice range for telemetering channels. It is relatively easy for the harmonics of these tones and the sum of these tones to appear in the voice range during the amplification, modulation, demodulation, and amplification of the combined voice and tones after and before the separation filters. The magnitude of the tone interference in the voice band is proportional to the per cent distortion in the audio range. If one assumes that a given carrier channel has as little as 5 per cent distortion, then the harmonics of these tones may only be down 26 decibels in the voice range. That would mean that there would be tones at 580 cycles (two times 290) and 806 cycles (two times 403) due to harmonic distortion.

However, there is a still more serious source of interference.[1] One can make a fairly safe assumption that the intermodulation distortion due to the addition of tones would be at least twice the per cent distortion. Based on our previous assumption of 5 per cent distortion, this would mean that a tone of 693 cycles (the sum of 290 and 403) would appear in the voice band and be only 20 decibels below the level of the fundamental tones. If one assumes that any one of the fundamental tones is 15 decibels below the normal voice level, these interfering tones would be about 35 decibels below the voice level. If this level of interference were of random noise character, it might be tolerable based on the judgment of a user, but a single tone or combinations of single tones would have to be 45 to 50 decibels below the voice to be tolerable based on tests we have made. This means that a complete carrier-current channel must have less than 2 per cent distortion to meet this objective. It is practically impossible to maintain as low a distortion as 2 per cent in a carrier channel as applied to a power line, especially when it is combined with speech signals which vary in intensity from time to time. The preceding assumptions which lead to the conclusion are very conservative, and an actual case can easily be less favorable. Discussion by the author is invited on this topic.

Also, in discussing the repeating of audio tones from carrier channel to carrier channel, the same harmonic distortion and modulation products become additive from channel to channel and work to the disadvantage of successive usage of this principle. The author indicates the use of equalizing amplifiers, involving filters at the by-pass points, and it would seem very desirable to

have excellent automatic volume control or automatic level control at these points to hold modulation of succeeding transmitters to a safe level, so excess distortion could not occur. Also, what safeguards would be taken against voice levels causing overmodulation of the transmitter when involved in transmitting both tones and voice, and thereby causing severe harmonic distortion of the audio tones? When any form of limiting occurs, intermodulation distortion increases as the square of per cent distortion and would become very severe in this type of operation. Filters can be provided to separate the telemetering and communication circuits so long as they remain in separate frequency groups.

The points raised in this discussion involve interference of the telemetering tones in the voice channels at a point where the filters are powerless to eliminate the spurious frequencies from the telemetering circuits in the voice frequency group.

The author described a method of transmitting several readings from several outlying points to a central point on a system by means of single side band transmission. Related to intermodulation distortion described previously, is the problem of receiving and detecting all these signals in a common receiver. Line attenuation changes in this case would not affect all signals alike and some safeguards would have to be taken to prevent serious distortion in the common receiver. If an automatic volume control is used to avoid distortion, this would allow strong signals to blank out the weak ones. The author should describe this method more fully.

In describing the double frequency scheme for combining relaying, telemetering, and voice communication, it is not clear how local blocking is prevented when an internal fault occurs. From the information presented, the protective relays would have to control both the voice transmitter and the relay transmitter and require something more than normal in the way of control. Perhaps the equivalent control is provided some other way.

In reviewing the various possible carrier circuits for telemetering, the author did not mention the use of narrow-band frequency-shift carrier equipment for telemetering. This method is now being widely used on both telephone lines and power lines at 5–20 kc for telephone lines, and 90–200 kc and 30–90 kc for power lines. However, a paper is already scheduled to be presented at a later date which will describe this system.

1. AN ANALYSIS OF THE INTERMODULATION METHOD OF DISTORTION MEASUREMENT, W. J. WATTES, W. R. HOWLETT. *Proceedings*, Institute of Radio Engineers (New York, N. Y.), volume 36, number 4, April 1948, pages 457–66.

M. A. Bostwick: Discussions by Thynell, Thomas and Lynch will be answered as a group as they all objected to classification of telemetering apparatus into three types namely: voltage, current, and impulse. This classification is advantageous as it tends to shorten the discussion of all types of circuits without omitting pertinent information. It is noted that Thynell states that "frequency type systems have been completely ignored," while Thomas and Lynch object to inclusion of frequency systems in the impulse classification.

The problems that are encountered in transmission of each type of signal, which have been mentioned by Thomas and Lynch, are of lesser importance. They should be considered, but are easily solved. This is borne out by experience. A highly accurate telemetering installation on the Union Electric Company of Missouri system, which employs impulse duration transmitters to control narrow-band audio frequency tone transmitters was recently described by R. G. Meyerand. Since the transmission of impulse rate signals is not of necessity limited to frequencies below that of the frequency-type telemetering transmitter, it is obvious that the problems encountered in transmitting these signals are similar.

In general, it can be stated that the width of the band of carrier frequencies that is used in a given channel will determine the amount of information that can be transmitted with a given accuracy, in a given period of time. This applies to all types of telemetering transmitters, impulse-duration, impulse-rate or frequency types. Consequently, the inclusion of these various transmitters in one classification was considered desirable.

Lunge calls attention to telemetering systems that were listed in the references, and states that, "Without an improved receiver it is difficult to understand how either accuracy or speed of response of the telemetering system could be increased." This is no doubt a misstatement. Accuracy involves both transmitter and receiver. Furthermore, the use of electronic controls permits use of higher impulse rates and increased speed of response, as he has pointed out.

Kenefake calls attention to a number of design details that are well known. Since the information primarily affects design, not use of the equipment, it was not considered to be properly a part of this paper. Very little data are available that accurately fix noise levels on power circuits. Because of this, the capabilities of the various types of carrier transmitters have been listed with factors of safety to assure operation through a quiet line when using a ten-watt transmitter. Larger factors of safety are used for carrier relay control circuits.

The filters, that are used to separate telemetering and voice circuits, are designed to give ample attenuation. Narrow band telemetering transmitters that were mentioned by Kenefake, were listed as crystal-controlled narrow-band equipment in the paper.

Economics of Long-Distance Energy Transmission

R. E. PIERCE
FELLOW AIEE

E. E. GEORGE
FELLOW AIEE

THE economic location of steam-electric generating stations is receiving intensified study, not only because of the tremendously increasing demand for electric energy, but because of changes that have taken place and are still occurring in the relative effect of certain primary controlling factors. These include changes in the relative effects of location and cost of alternate fuel supplies, cost of transporting alternate fuels, and cost of transmission of electric energy.

It has been rather usual practice to locate plants at adequate natural water supplies and adjacent to fuel sources or transportation, with transmission of the energy electrically to the load. If the transmission of electric energy produced from fuel involved distances in the order of 200 miles, the economics of this practice was questionable. Even the economics of transmitting electric energy produced from water power for distances of 200 to 300 miles was not too favorable unless the amounts of power to be transmitted were relatively large and competing fuel costs relatively high.

This paper presents comparative summaries of the cost of transmission of energy in the form of coal, gas, oil, and electricity. Relative costs of the three fuels near their sources are shown in Figure 7 for the period 1922 to date, illustrating the extent to which the relationship between fuel costs has changed within the last few years. From these data it is apparent that consideration must be given, in the economic choice of steam power plant location, to present day costs of fuel at the nearest sources and present day costs of transmission of the fuels versus the cost of transmitting electricity. The problem is analyzed only under average or typical conditions, but the results give an indication of the need for basic studies in each particular situation and give a fair approximation of the answer for average conditions.

The study of any particular problem involves many fields of engineering and it is therefore expedient to analyze only the basic considerations in this paper, which is devoted chiefly to the transmission of fuel energy. This paper concerns itself entirely with the straightaway hauling of large amounts of energy over long distances.

Electric Transmission

For a long time it has been generally considered that the high-voltage transmission line is the preferred means of carrying energy. This is largely due to its flexibility in distribution and conversion rather than any inherent economic superiority in transmitting large blocks of energy on a straightaway basis.

Analysis shows that the major factor affecting a comparison of costs of high-voltage transmission between 1915 and 1945 has been a doubling of permissible line loading under ordinary operating conditions. Technical improvements in telemetering, automatic load control, high-speed protection and reclosing, excitation, lightning protection, and the close co-ordination of these factors have permitted loadings of high-voltage lines close to the stable limits set by steady-state conditions. These increases in operating capacities have in large measure offset the increase in investment costs during the last 30 years.[1]

Basic transmission line designs have not changed materially in the last 30 years, except for improved lightning protection, and transmission line costs in 1945 were not much higher than after World War I. There has been a tendency to use larger conductor sizes and to use higher current densities than in the early days of high-voltage transmission. The cost of terminal equipment such as oil circuit breakers, transformers and synchronous condensers has increased and is responsible for some increase in the overall cost of electric transmission.

Transmission cost may be placed on a mileage basis. A study made in 1945 by one of the authors developed a cost of firm high-voltage transmission expressed by the formula

$$\text{mills per kilowatt-hour} = 0.50 + \frac{(0.47 \times \text{miles})}{100}$$

In 1947 Crary and Johnson[2] presented data from which can be developed a similar formula for transmission cost:

$$\text{mills per kilowatt-hour} = 0.30 + \frac{(0.47 \times \text{miles})}{100}$$

These formulas show substantial agreement in spite of independent assumptions as to line loading, losses, voltage, fixed charges, and so forth. Both of these formulas are for 50 per cent load factor and 1945 price levels in the United States.

The unit cost is substantially independent of transmission voltage, and of the amount of power transmitted, provided both are high. All figures for electric transmission in this paper (and in the Crary and Johnson paper[2]) assume optimum loads and voltages for various distances (200,000 kw or more on long hauls).

Figure 1 shows estimated costs of

Paper 48-195, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 7, 1948; made available for printing July 12, 1948.

The authors wish to acknowledge the assistance of associates in Ebasco Services Incorporated in the preparation of this paper, particularly S. B. Flagg, mechanical engineer and E. P. Kramer, rate consultant, in the assembly of basic data.

Figure 1. Costs of electric transmission

Figure 2. Railroad rates on coal

electric transmission, including fixed charges, losses, operation and maintenance, as of September 1947 price levels, for 50 and 90 per cent load factors. The increase in costs of transmission between 1945 and 1947 was estimated at about 35 per cent. Expressed by formulas, these costs are

For 50 per cent load factor

$$\text{mills per kilowatt-hour} = 0.54 + \frac{(0.63 \times \text{miles})}{100}$$

For 90 per cent load factor

$$\text{mills per kilowatt-hour} = 0.30 + \frac{(0.35 \times \text{miles})}{100}$$

Competitive Means of Transmitting Energy

Ordinarily, one thinks of hauling coal by rail and transmitting power electrically as the most typical competitive methods. However, this is only a small part of the picture. In a number of economic studies for electric and gas utility systems, oil refining companies, chemical companies, and transportation systems, various methods of transporting energy have been studied and compared including the following.

1. Coal by rail
2. Coal by ship
3. Gas by pipe line
4. Oil by pipe line
5. Oil by rail
6. Oil by tanker
7. Electricity by transmission line

In some cases the published class tariffs of common carriers may be assumed to accurately represent the cost of transporting fuel in moderate quantities and at commercial load factors to a power plant, but there is frequently evidence that the company contemplating construction of a large base load power plant might do better to seek special contract rates, or construct its own pipe line, because the published class tariff may be based on low-load factor operation for a multiplicity of customers with low diversity. As a lower limit of gas and oil pipe-line charges for very high-load factor, large-scale, long-haul operation, the estimates for large pipe lines given herein are fairly representative. These estimates assume private ownership and operation and maximum continuous use.

In comparison of various methods of transporting energy annual load factor is important, because fixed charges are greater than operating expenses, except possibly in the case of rail hauls. In the use of published coal tariffs of common carriers, the tariffs are assumed to be sufficiently independent of load factor to permit comparison on an energy basis in the charts shown in this paper.

Transportation of Coal

Figure 2 shows a scatter diagram of freight rates of coal, with dollars per net ton plotted against railroad miles between mine and destination. The individual rates plotted are for September 1944[3] but the solid straight line drawn to approximate the average relation between freight rates and mileage includes increases up to September 1947 but does not include the increases authorized late in 1947 and early in 1948. For this particular commodity there is a wide discrepancy in cost of transportation per ton. The spread in rates for any particular mileage is not due in any great degree to the geographic location and consequent difference in territorial level of freight rates, except possibly in mountainous areas, such as Virginia and West Virginia. Some of the rates are influenced by truck and barge competition. Rates under favorable conditions may be $.40 per ton under the average line, while rates under unfavorable conditions might well be $.50 to $1.50 a ton higher.

Due to the spread in rates it is imperative to analyze local conditions for the final answer in any particular case in which the freight rate on coal as determined from Figure 2 seems to be competitive with other means of transmitting energy.

No summary of costs of hauling coal by ship or barge is developed herein, but there is frequently keen competition between hauling coal by water and substitute haul by rail for the inland river and coastal routes. Such situations also necessitate detailed analysis.

Transportation of Gas

Figure 3 is a diagram of pipe line charges for natural gas. Since there are few common carriers for this service, the costs of transportation have been obtained by taking the wholesale industrial schedules of the gas utilities[4] and subtracting an estimated average cost of production and gathering at the sending end. For this analysis, $.08 per thousand cubic feet has been assumed as the sending end cost and has been deducted from the delivered cost to arrive at the cost of transmission. There is a wide spread in these rates. This might be expected since rates for both tariff and special contract types of services are included. Most of the tariff rates are for interruptible service, requiring oil standby service.

Because most of the gas utilities are engaged in retail operations as well as pipe line operation, there is no assurance

that the customers' rates reflect the portion of the total cost assignable to bulk pipe line operation. Some of the rates are probably promotional and some of them are based on long-term supply contracts which cannot be renewed without increase in cost. However, the long-haul contract rates for interruptible service to utilities check fairly well with the estimated cost for a large gas line under private operation, handling gas at maximum capacity at 100 per cent load factor (marked by an X on Figure 3). Apparently interruptible rates are nearly independent of load factor.

Transportation of Oil

Figure 4 shows a similar diagram of pipe-line tariffs on crude oil,[6] with dollars per barrel plotted against airline mileage between the gathering station and destination. There is comparatively small spread between the rates for any given mileage, and the average line is therefore fairly indicative. Most of the rates selected for the graph are those involving only one pipe-line company for each delivery, since this is more representative of competitive conditions. Some of the pipe line companies are common carriers without refineries or other operations and of necessity they establish tariffs proportional to their actual cost of pipe line operation. The load factor applying to typical pipe-line operation is unknown. An estimated cost, based on published data, for the Big Inch Lines at full capacity and 100 per cent load factor, assuming private operation is shown by the X on Figure 4. In many pipe lines, crude oil and lighter refinery products are handled interchangeably, but ordinary fuel oil for power plant use is too viscous for long haul by pipe line. Therefore oil for power plant or ship fuel requires a terminal refinery near the power plant, unless tanker haul is geographically feasible.

The handling of oil by rail in tank cars is somewhat of a retail operation as compared with pipe-line delivery. It is generally limited to points where there are no pipe lines and where there is insufficient traffic to justify a pipe line.

The hauling of oil by tanker is much cheaper than other means but is limited by geography to river and coastal terminals. Probably the best summary of costs of transporting oil is that given in the pamphlet "Economics of the Petroleum Industry," by Joseph E. Pogue of the Chase National Bank. Two pertinent quotations follow.

"For liquids available in sufficient volume with a concentrated market, the pipe line affords the most efficient form of overland transportation. While capital costs are substantial, rights-of-way are not expensive, the operation of the system is automatic to a high degree, movement is continuous, and there is no problem of two-way traffic or return movement of empty facilities. Because of these advantages and the technical proficiency of modern pumping systems, the average cost of pipe line transportation probably does not exceed four mills per ton-mile, which contrasts with an average cost of movement by rail of approximately eight mills per ton-mile. Thus no natural competition can persist between oil pipe lines and the railroads."

"Because of automatic loading and bulk, the oil tanker represents the ultimate in transportation efficiency, exceeding that of the pipe line. Comparative costs per ton-mile are approximately 8.3 mills by rail, 3.2 mills by pipe line, and 1.25 mills by tank vessel. In consequence the tanker competes with the pipe line and diverts as much traffic as the geographic pattern permits."

The costs quoted previously refer to conditions in 1939, but present-day tariffs for 300- to 500-mile pipe-line haul are still around 3 or 4 mills per ton-mile. By using terminal storage tanks, oil tariffs are made on a volume or weight basis, nearly independent of load factor.

Comparative Costs of Transporting Energy

Before making comparisons between transportation of energy by various means, it should be pointed out that comparison between transmission costs only for gas, oil, and coal are likely to be misleading because there is so much difference in the costs of these fuels at their sources. This is particularly true under present conditions.[8] In the past, it was usual to assume that there was no choice of fuels, or that a definite selection had already been made, and that the only comparison necessary was between transportation of the particular fuel and electric transmission. The picture is very much different now from that 10 or 15 years ago. Gas and oil are now transported by pipe line in large quantities for distances over 1,000 miles. Mechanization of coal mining in the future may offset increasing labor costs. Fuel oil is no longer a by-product derived from crude oil in a ratio fixed by the natural chemical composition of the oil. Developments in petroleum chemistry now provide considerable flexibility in the percentages of the various refinery products. Therefore the future price of crude oil is likely to be highly susceptible to technical and economic factors in the whole petroleum industry. The low cost of transporting oil and gas by pipe line as compared with the cost of hauling coal by rail together with the current progress in converting coal to gas or oil may still further upset economic relations between the three fuels in the next few years.

It should likewise be kept in mind that the present activity in construction of gas and oil pipe lines is likely, within the next few years, to greatly increase the number of localities which have these fuels available in quantity at competitive prices.

Figure 3. Pipe line rates on gas

Figure 4. Pipe line rates on crude oil

Comparisons between coal, gas, oil, and electric transmission are made easy by using the following nominal conversion factors and efficiencies.

1 barrel of oil = 6,250,000 Btu = 500 kilowatt-hours
1,000 cubic feet of gas = 1,000,000 Btu = 80 kilowatt-hours
1 ton of coal = 25,000,000 Btu = 2,000 kilowatt-hours
1 kilowatt-hour = 12,500 Btu (modern steam plant)

Figure 5 shows costs for transporting energy by various means with mills per kilowatt-hour plotted against airline miles. It is assumed that pipe-line miles are substantially airline miles. To obtain the costs in cents per million Btu, multiply the mills per kilowatt-hour by eight.

All data for transportation of fuel are commercial rates, using the average lines of Figures 2, 3, and 4. The average for gas has been taken as halfway between maximum and minimum rates of Figure 3. The electric transmission costs are the same as those shown in Figure 1. These electrical costs reflect a 35 per cent increase in price level from 1945 to September 1947, compared with approximately 15 per cent increase in freight rates, pipe line tariffs, and so forth.

Although Figure 5 is based on estimated averages, it answers in part the basic question as to how electric transmission compares with other means. At 50 per cent load factor, the high-voltage transmission line and the coal car are generally competitive for short distances only.

The situation for base load plants is highly competitive. Load factors of 96 per cent or more are involved. At 90 per cent load factor (base load operation) electric transmission may well be as cheap as coal for any distance, and as cheap as gas for distances up to 100 miles.

Transmission line costs are almost exactly inversely proportional to load factor, whereas the charges for pipe line transportation as shown by Figures 3 and 4 are largely independent of load factor, being based on use of storage, substitute fuel or curtailment of service.

It should be noted that the cost of transmitting energy by gas pipe line is two or three times as high as the cost of transmitting energy by oil pipe line.

Figure 6 is the same as Figure 5 except that total costs are shown on a capacity basis instead of an energy basis.

Figure 6 facilitates comparisons with hydro power. There is no choice of means of transmission when using hydro power. Such simple and tangible expressions for transmission cost easily demonstrate that so-called "cheap power" is not cheap if it has to be transmitted electrically to a distant market. The slope of the electric transmission cost lines in Figure 5 and Figure 6 gives directly the difference in cost of transmission for different distances, and is approximately 0.63 mill per kilowatt-hour per 100 miles or $2.78 per kilowatt per year per 100 miles, both for 50 per cent load factor. At lower load factors these unit cost differentials per 100 miles would be even greater. It is readily apparent therefore that with the investment cost of a hydro plant generally greater than for a similar size steam plant, hydro power would be more costly than steam power by the time it was delivered a few hundred miles away. In areas of low fuel cost, hydro power transmitted even shorter distances would be more expensive than steam power.

Costs of Fuels at Sources

Figure 7 shows the relation between prices of coal, gas and oil for the years 1922 to date. Values plotted in this figure are the average yearly realized prices of bituminous coal at the mines,[7–9] fuel oil at the refineries in the south Texas oil fields[10,11] and natural gas at the wells.[8,12,13] Coal and gas annual figures are averages for the entire United States, compiled by the Department of Interior. Oil figures are from the Petroleum Almanac. The values for the third quarter of 1947 are estimates, based on spot prices. Old contract prices, which largely determine realized prices are still considerably lower, but in a rapidly rising market, spot prices are considered more indicative of new contracts.

From Figure 7 it will be seen that the prices of coal and gas, at the sources, were about equal, on an energy basis, prior to 1934. Since that time, the price of coal has risen very rapidly and coal now costs about three times as much as gas for the same amount of energy. In those areas which were not too far distant from both coal and gas sources, the two fuels were competitive for a long time. This is no longer true, and as will be shown later, gas can be carried by pipe line a considerable distance and still be competitive with coal near the mine. Under such conditions the choice of fuels can no longer be made on an arbitrary or noncompetitive basis.

Prior to 1945 fuel oil cost about twice as much as coal or gas on an energy basis. This explains why fuel oil was used only for standby purposes, except in a few plants located a long way from the coal and gas fields and yet cheaply accessible by tanker from the California, Texas, Mexico or Venezuelan oil fields. Today the spot price of crude oil is about three times the cost of coal and about nine times the cost of gas, thus making it very expensive for standby service if such service is required many hours in a year. Present conditions in the oil industry are

Figure 5. Costs of transporting energy-mills per kilowatt-hour

Figure 6. Costs of transporting energy-dollars per kilowatt per year

Figure 7. Comparison of fuel costs at source

Figure 8. Costs of fuel plus transmission

reported to be largely due to shortages of pipe line and refining capacity. These should improve when sufficient steel becomes available and when more foreign oil fields have pipe lines completed to tidewater terminals.

It therefore appears that the choice of normal fuel and of standby fuel for a power plant justifies extensive study for each particular project and that this situation will continue for some time to come.

Delivered Costs of Energy

Figure 8 shows a comparison of present day "delivered costs" for the three fuels, coal, oil and gas. Delivered cost is intended to denote only the cost of the fuel itself and the cost of its transportation. This is obtained by combining the information on 1947 fuel costs at the source, Figure 7, with that on cost of transporting the respective fuels, Figure 5.

The information on Figure 8, delivered fuel energy, and Figure 1, transmission of electric energy, with certain adjustments for differences in other production costs could be combined in several ways to show comparative costs of electric energy produced from alternate sources and transmitted different ways and different distances to a given load center.

As one example, assume that it is desired to compare gas which could be transported by pipe line 300 miles to a large load center with hydro power located 100 miles from the load center. By superimposing on Figure 8 a line representing the cost of electric transmission as shown by the dashed line on the chart, it is determined that, aside from differences in other fixed charges and production expenses, the hydro energy would be worth 0.34 mill per kilowatt-hour, based on the cost of the alternate gas fuel. (See *A* on chart). In this comparison it is assumed that electric transmission is at 50 per cent load factor, limited by the characteristics of the hydro project. Typical charges for pipe-line transportation of gas for utility service (interruptible contracts) have been considered to be applicable.

Theoretically, a power plant might be located at the fuel source, at the load, or at any point in between.

Practically, a low-load factor steam plant should be located at the load (because the incremental cost of electric transmission is higher than other means of transmission) except for distances under 200 miles with coal fuel from a mouth-of-mine plant. Such a plant (with coal delivered to the bunkers from mine cars—no rail switching charges involved) would have about a half mill saving to offset the incremental cost of electric transmission. A high-load factor power plant burning coal would have to be studied in detail to determine the best location. If feasible, mouth-of-mine location would generally be most economical.

For oil or gas fuels, pipe line transmission is usually the most economical, regardless of distance or load factor.

Conclusions

1. Technical improvements in the art have in large measure offset increases in cost of electric transmission.

2. Cost of electric transmission for optimum loads and voltages can be expressed as a linear function of power and distance.

3. Cost of fuel transportation can be expressed as a linear function of energy and distance.

4. Electric transmission at low load factor is competitive with hauling coal by rail for only short distances.

5. Electric transmission at high load factors (base load plants) is competitive with hauling coal by rail for any distance (up to several hundred miles).

6. Electric transmission is generally much more expensive than transporting energy by gas or oil pipe line.

7. The cost of transmitting energy by gas pipe line is several times as high as by oil pipe line.

8. Tanker transportation of oil costs only about half as much as pipe line transportation.

9. The costs of fuel and its transportation to load centers are usually the dominant factors in determining the market value of hydro energy.

10. Coal and gas are no longer competitive, either close to both sources or several hundred miles away. Gas may be carried several hundred miles and still compete with coal near the mine.

11. Fuel oil is now too high for use except for standby service, unless tanker haul is available and other fuel sources are several hundred miles distant.

12. A mouth-of-mine steam plant is economical if the plant load factor approaches base load conditions.

13. If gas or oil is to be used for fuel, a power plant location near the load will almost always be most economical.

Discussion

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): The authors are to be complimented on the work that they have done on a very important and difficult subject. The relative economics of different sources of energy, each transmitted by the best technical means available, needs further discussion and as a prelude to such discussion, further work needs to be done on the development of what the underlying economics and potentialities are. The authors have made a contribution of note in that direction, but a great deal more work still remains to be done. The authors have, however, perhaps under-estimated the remaining gaps. A point, too, that needs to be remembered is that in their studies, costs and tariffs have been mixed. Thus, transmission line costs, based upon fixed and operating costs of facilities necessary to provide electrical transmission, and cost of hauling coal by freight, based upon existing tariff schedules, may each be cost to the ultimate consumer, but they are not strictly comparable costs and certainly are not comparable when one considers the problems that may face the common carriers of the country as a result of continuing rises in cost of labor, materials and supplies and in cost of railroad facilities.

Some of the conclusions of the authors, therefore, can be accepted and others need considerable modification. It is particularly important to point out that broad conclusions, based upon averages, are liable to lead to grave error, if they are not accompanied by specific studies for each particular project. As an illustration, Figure 8 of the paper, representing September 1947 data, shows a typical fuel cost in mills per kilowatt-hour for three fuels, one of them being coal coming in by railroad in a range of distance from zero to 1,400 miles. For coal fuel, the figures vary from 2.8 mills for at-mine location to 6.7 mills for a distance of 1,400 miles. This is based upon an average performance of 12,500 Btu per kilowatt-hour. However, on an actual system the weighted average data for the year 1947, where approximately 10,000,000,000 kilowatt-hours were generated by coal burning capacity, with coal delivered distances up to 200 miles, and with plants having performances running from 10,200 Btu to approximately 30,000 Btu per kilowatt-hour, the following weighted averages figures prevailed:

Btu per kilowatt-hour,	13,689
Fuel cost per kilowatt-hour,	2.14 mills

R. E. Pierce and E. E. George: The comments of Sporn are appreciated, especially in view of his long experience and interest in this subject.

The authors agree that pipe line tariffs and freight rates have been used as costs in the absence of any better information. However, while the paper calls attention to these instances, it might be noted that the figures for gas pipe lines and oil pipe lines, based on published tariffs, have been compared with estimated costs on modern pipe lines now in operation or under construction. Most of the electric utilities interested in securing transportation of fuel are more likely to depend upon concerns engaged in this business than to enter the business themselves. Therefore, tariffs rather than costs would usually govern.

It is felt that the figures of Sporn showing an average 1947 fuel cost per kilowatt-hour of 2.14 mills are not too far out of line with the data in our paper, considering that the costs Sporn quotes are undoubtedly based on contracts which would lag behind spot prices in a rising market. Whether one buys coal or mines it himself, his fuel costs for an additional plant requiring new fuel sources today will of necessity be much higher than average figures for an existing system.

Since the preparation of the paper in 1947, there have been extensive changes in the prices of fuels. These changes do not contradict the general conclusions. However, in the comparison in the second paragraph under Costs of Fuels at Sources, the figures given would read about as follows if brought up to the third quarter of 1948:

Approximate Costs of Power Plant Fuels at Sources

Gas	$.10 per million Btu
Coal	$.20 per million Btu
Oil	$.40 per million Btu

Development of the Transmission System From the Grand Coulee Power Plant

B. V. HOARD
MEMBER AIEE

E. E. HELWITH
ASSOCIATE AIEE

THE transmission system of the Bonneville Power Administration transmits the power from the Grand Coulee generating station and from the Bonneville generating station, both situated on the Columbia River, to three major load areas in eastern Washington, western Washington, and western Oregon (Figure 1). The Bonneville generating station has had its full capacity of 570,000 kw installed since December, 1943. Since April, 1948, Grand Coulee has had nine of the ultimate of 18 generators installed, and plans call for rapid installation of the remaining nine generators. With 18 generators at Grand Coulee, the actual peak output will be in excess of 2,160,000 kw.

A series of studies has been made, and it appears that by proper system arrangements this amount of power can be handled economically by the construction of ten 230-kv lines and three to four 115-kv lines. The ten 230-kv lines will carry approximately 2,000,000 kw with an average transmission distance of 180 miles, while the 115-kv lines will handle the remaining power supplying loads near the vicinity of the generating station. With all generators peaking this plan will result in an average load at the sending end of each 230-kv line of about 200,000 kw per line. The system is unique in that the very large amount of generation concentrated at one location makes it possible to take advantage of multiple transmission circuits to a load area. For such a system as compared to one which, for example, has just two lines to a load area, the loss of any one transmission circuit is relatively a smaller percentage of the total transmission capability. Hence each line in the system can be loaded both normally and during emergencies to a considerably greater amount than would otherwise be possible in the two circuit system, without any sacrifice in transient stability, thereby providing greater economy of design.

In view of the fact that the three load areas served by the Bonneville Power Administration are widely separated, several questions naturally arise: should all lines be solidly bussed at the Grand Coulee switchyard; should lines and generators supplying each load be completely segregated; or should a compromise arrangement be used which connects busses through some reactance? This paper, as one of its major objectives, presents the interesting results of the investigation made to find the answers to these questions. A second major objective of the investigation was to determine system arrangements which would result in a high value of transmission capability and operating flexibility without requiring circuit breaker duties greater than it was possible to manufacture.

In order to carry rapidly growing system loads, plans call for rapid installation of Grand Coulee generators and the building of transmission circuits as indicated in Table I.

To obtain a more general picture of the problems encountered it may be well to explain that the Grand Coulee power plant and dam were constructed as a multiple-purpose irrigation and power project under the control of the United States Bureau of Reclamation. The Bonneville Dam and powerhouse, near Portland, having navigation features, were built and are operated by the United States Army Engineers. The Bonneville Power Administration is designated as the transmission and marketing agency for the electric power output of both dams, as well as other dams in the Columbia Basin which are now planned or being built.

From the standpoint of the ultimate development of the Columbia River and its tributaries, the Coulee and Bonneville projects are the first two of a series of many to be constructed in the Columbia River Basin, having a possible economical development of something over 10,000,000 kw. Of these additional dams, initial steps have been taken for the construction of McNary Dam on the Columbia River (966,000 kw peaking capability). Figure 1 shows the 1948 transmission system and generating stations geographically with probable major transmission system additions up to 1952, and with the McNary, Detroit, and Hungry Horse Dam sites indicated.

Somewhat farther in the future are the Foster Creek and Hells Canyon developments, the four plants on the lower Snake River and Albeni Falls on the Clark's Fork River. The development of a transmission system for Grand Coulee is only a part of a more comprehensive program for an over-all transmission system which must be planned to handle the output of all these future stations, and preliminary studies are now being made on this problem.

With respect to immediate system

As of	Number of Generators Installed	Number of 230-Kv Transmission Circuits	Capability of Station 120,000 Kw per Unit
December, 1948	9	6	1,080,000
December, 1949	12	8	1,440,000
December, 1950	15	9	1,800,000
December, 1951	17	10	2,040,000
December, 1952	18	10	2,160,000

Paper 48-196, recommended by the AIEE transmission and distribution and power generation committees and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 14, 1948; made available for printing July 20, 1948.

B. V. HOARD and E. E. HELWITH are both with the Bonneville Power Administration, Portland, Oreg.

planning, the development of a transmission system which will handle approximately 2,200,000 kw of Grand Coulee generation, with necessary switching facilities and operating flexibility at the Grand Coulee switchyards, and which will provide transmission system stability and over-all economy, becomes a major undertaking. The switchyard arrangement determines how the lines and generators will be connected together, and the type of connection will produce varying effects on system transient stability as well as on steady-state loadings. It will determine oil circuit breaker interrupting duties, which are much higher than could be handled by past circuit breaker designs of 3,500,000 kva. These and other requirements had to be achieved at the most reasonable cost consistent with reliable service. Investigation of how these requirements could be met by the various plans became a joint responsibility of engineers of the Bonneville Power Administration system and of the Bureau of Reclamation.

Those aspects of the problem involving location of system loads and transmission line capabilities, line interconnections at Grand Coulee, power transfer capacities, and system relaying and stability, were of vital interest to Bonneville Power Administration and were worked out with the help of Bonneville Power Administration's a-c. network analyzer. Problems of physical plant layout, electrical control and switching facilities, and design, relaying and construction of the switchyards, were the province of the Bureau of Reclamation.

Figure 1. December, 1948, transmission system with probable 230-kv additions up to 1952 and some future power site locations

Preliminary Design

Original design called for isolated bus sections with two parallel lines and two 108,000-kva generators per circuit. Circuit breakers of 2,500,000 kva were the largest available. This arrangement would produce line loadings of 108,000 kw and obtain reliable operation over each pair of long 230-kv lines. If three generators were to be isolated on two long lines normal loads of 162,000 kw per line would occur which was considered excessive from a transient stability standpoint.

System Development

The first lines built were two 230-kv circuits to Portland via Midway and Bonneville Dam, and a line to Seattle (Covington substation), Figure 1. In addition a tie line was constructed between Seattle and Portland, which supplied major intermediate loads at Chehalis and Longview substations. It became necessary for reliability purposes to close the 230-kv loop at the Grand Coulee switchyard rather than synchronize through 607 miles of line. Then, two 230-kv lines were built to Spokane to supply war loads. It was necessary to synchronize these lines also at Grand Coulee switchyard with the lines to the Puget Sound and Portland areas. Otherwise relatively large synchronizing surges would have to take place through other lower voltage ties owned and operated by other agencies. It was not possible to isolate the Spokane load because this would prevent the importation of power from Montana into the western areas where it was critically needed.

After the addition of the fourth Grand Coulee generator to the common 230-kv bus, the 2,500,000-kva circuit breakers became overstressed. Circuit breakers with 3,500,000-kva interrupting rating became available and an interleaved line system, Figure 2, with two busses, four generators, and three lines per bus section was developed to carry through the war emergency. Synchronizing between busses was obtained through the interleaved lines. This arrangement has been described in a paper by Hoard and Bills.[1] It served well under the handicap of shortages of material, and a shortage of generation in some areas. Normal line loadings of over 170,000 kw have been attained with transient stability. This bussing arrangement will continue to operate at Grand Coulee until November 1948, when plans for major changes will be put into effect. These plans are described in a companion paper prepared by engineers of the Bureau of Reclamation.

Ultimate Comprehensive Design

Meanwhile, extensive transient stability studies on the Bonneville Power Administration network analyzer established the fact that through development of a proper high-voltage grid network the ultimate system could be designed for an average normal loading of 180,000 to 200,000 kw per 230-kv line, with the aid of suitable circuit breaker facilities and high-speed relaying, while still preserving transient stability through all reasonable fault conditions. An investigation of several high-voltage bussing schemes was undertaken to separate those having the most favorable transient stability properties for consideration in the more detailed design. By development of a bussing scheme which would give transient stability at line loadings of 200,000 kw, the peak output of 16 generators at 125,000 kw per generator could be handled over ten 230-kv transmission lines, assuming the spare generator in operation

Figure 2. Interleaved line scheme placed into operation during the war

and two generators reserved for 115-kv supply, instead of the 15 or 16 230-kv lines considered in the original design.

A large saving over the original design (using isolated busses) could be made since five lines would be eliminated. Allowing some increase in cost to develop the grid system at Grand Coulee and at step-down substations, due to larger circuit breakers, an over-all saving of from $20,000,000 to $25,000,000 is indicated. Obviously, isolating the system into units of two lines and two generators without synchronizing ties between busses at the generating station is not an economical solution nor is it practical to place three generators on two lines, as the emergency line loading would be 360,000 kw after a faulted line section had been removed, and there would be no possibility of maintaining transient stability. Another major disadvantage of the isolated system is the lack of operating flexibility when more or less power must be supplied to a particular load area. Also, other existing ties between major load areas which are owned and operated by other agencies would have to be opened to prevent synchronizing surges normally, and prevent instability during emergencies.

Bussing all generators and lines without reactance between bus sections supplies the greatest operating flexibility; however, the circuit breaker short-circuit duty for 3-phase faults near Grand Coulee becomes well over 11,000,000 kva and still higher circuit breaker duties are calculated for line-to-ground faults.[3] Besides the high circuit breaker duty, there are some disadvantages to straight solid bussing which will be discussed later. The design which is finally selected usually ends up as a compromise, but it should meet the following requirements:

1. Maintain steady-state and transient stability under anticipated distribution of ultimate peak loads.

2. Provide adaptability of the transmission network to accommodate large shifts in load without difficulty and without severe unbalancing of line loadings. This feature arises because the Bonneville Power Administration transmission network serves as the main interconnecting medium to coordinate the differing seasonal requirements of various other utilities for over-all water storage and utilization. Other shifts in line loading will occur as new generating stations are connected into the grid.

3. Either limit the short-circuit interrupting duties of circuit breakers or make certain that sufficiently large circuit breakers can be obtained to meet the requirements. It was considered desirable to obtain circuit breakers of high enough interrupting rating to permit high-speed reclosing following the occurrence of line faults. Another important factor was that single-line-to-ground faults in the vicinity of Grand Coulee, with all transformer neutrals grounded, would exceed 3-phase faults by approximately 15 per cent.

4. Limit the normal generation on any one bus section without sectionalizing circuit breakers to three generators (360,000 kw) so that in the event of the loss of a bus section, spinning reserves would pick up and carry the load. The 360,000 kw corresponds to approximately 10 per cent of total generation in the interconnected systems of the Northwest area in 1948.

5. Provide facilities to divert the power output of up to five generators to water pump operation over considerable periods without seriously unbalancing the transmission line loadings or the ability of the system to withstand transient shocks.

6. Provide for supplying a large block of future off-peak power to potential research plants.

7. Provide adequate general operating flexibility and maintenance facilities.

In short, the method to be used when connecting lines and generators together at Grand Coulee actually influenced the problem of the arrangement of a considerable part of the entire transmission network and vice versa.

Types of System Considered

Three basic types of transmission system were studied in relation to the foregoing requirements:

1. A system of parallel line pairs fed from busses electrically connected through various amounts of reactive impedance closed into a ring bus. As a special case, a solid bus is obtained when the reactive impedance becomes zero.

2. Extension of the interleaved line[1] idea to 18 generators.

3. Parallel line pairs fed from isolated busses.

Numerous arrangements and modifications of the foregoing types were investigated, totaling perhaps 30 schemes in all. Early in the study, because of economic and operating flexibility reasons already discussed, the isolated bus arrangement (scheme 3) was discarded.

From the standpoint of a preliminary analysis, scheme 1, with no reactance, that is a solid bus, appears to have special advantages over scheme 2 because of the ability to transfer reasonable amounts of power through the bus without shift of generation and with reasonable independence of load distribution on outgoing lines, but if this bus requires sectionalizing circuit breakers to meet the 360,000 kw limitation per bus, its cost will be greater than that of scheme 2. Still greater costs are involved for scheme 1 when reactors are used between bus sections, also the installation of reactors in the ring bus has the disadvantage that a future bottleneck may develop if the current carrying capacity is not sufficient.

One starting point for the ring bus (scheme 1) is found in the results of a paper by Bills and MacArthur,[2] in which transformers with multiple windings, Figure 3, furnish sufficient isolation between high-voltage busses to limit faults, and at the same time allow power to shift from bus to bus and furnish a path for synchronizing torques.

A modification was worked out for a five-section ring, using some standard 2-winding transformers and some transformers with duplex high-voltage windings, Figure 4. Each tie bank of transformers would have a rating for each of two high-voltage windings of 170,000 kva and 260,000 kva for the low-voltage winding, with an impedance of 38 per cent between high-voltage terminals, and 20.5 per cent from each high terminal to the low terminal on a 170,000-kva base. This starting point was based on earlier analyzer studies showing low circuit breaker duty and excellent stability for single-circuit faults on the system. When it appeared that 3-winding transformer manufacturing difficulties and costs would be excessive, and there would be installation difficulties in the existing left powerhouse, this scheme was discarded in favor of bus tie reactors as indicated on Figure 5. Electrically, the synchronizing torques produced by high-voltage bus tie reactors or by 3-winding transformers can be made substantially equivalent through selection of reactance values.

Transient stability studies were made for single-circuit faults, a major portion of which were located just outside the Grand Coulee switchyard, the worst spot in terms of system shock within the area affected by Grand Coulee bus design.

Fault clearing time was taken as 4.5 cycles at the near line terminal and nine cycles at the far end of the line. Although 3-phase faults are infrequent, they were used for simplicity, and for the fast clearing times considered, the shock of a 3-phase fault is very little greater than for the more prevalent 2-phase-to-ground faults.

When reactors were used, it was found that for faults near Grand Coulee the system was more stable, that is, a lower value of angular difference occurred between generator rotors at the point of maximum swing than when the reactors were bypassed (a "solid bus"). It will

Figure 3. Three-winding transformer ring bus scheme

Ring developed on low-voltage side

be recalled that these bus-tie reactors introduce two opposing tendencies:

1. If the fault could be cleared in zero time, the shock to the system would be identical to that introduced by removal of the line section by switching only. In that event bus reactors would be a pure liability, for they introduce additional reactance between portions of the system.

2. However, when the fault is cleared in a finite time, the opposing effect occurs, namely, during the fault period the reactors decrease the short-circuit current, maintain higher voltage and higher load on unfaulted busses and increase the synchronizing power between machines, so that the generators unload less, accelerate less, and therefore stability is increased. Even for the short clearing time of 4.5 cycles this effect is sufficiently great that it appears worthwhile to introduce some reactance between busses to improve stability, apart from its value in reducing circuit breaker duty.

For the system studied, the effect of bus reactors was to aid stability for line and bus faults at the sending-end bus, but reduce stability for faults at substations one line section distant from the generating station. However, a net advantage is obtained since faults on or near the generator bus are the more severe and determine the stability limit of the system. These results were found for 4.5-cycle clearing of bus faults and 4.5- and 9-cycle sequential clearing of lines.

Optimum Reactor Impedance

Insofar as the Coulee bus design could influence stability, it had been planned to secure transient stability both for single-circuit faults and for bus faults at Grand Coulee. As the study progressed, it began to apprear that the effects of multiple paths in the high-voltage grid were greater than had been anticipated and that by lowering the impedance of the bus-tie reactors and arranging to take care of the increased circuit breaker

Figure 8. Relative circuit breaker duty and stability of bussing schemes at Grand Coulee

Seventeen generators, no pumping

duty resulting therefore, it would be possible to raise the criterion to maintain stability following the occurrence of simultaneous double-circuit faults. Such faults have been infrequent on existing parallel lines of single-circuit construction, but experience on the double-circuit tower line from Grand Coulee to Spokane has shown that their frequency is greater when parallel lines are placed on double-circuit towers. Some of the future lines to be built out of Grand Coulee will be of double-circuit construction because of lower over-all cost, and because of crowded right-of-way at certain locations; therefore simultaneous double-circuit faults had to be seriously considered.

A double-circuit fault on parallel lines became the criterion for which to design, and the impedance of bus reactors at Grand Coulee was changed to determine the value which would give optimum system stability. The index of comparison was taken as the maximum angular difference reached during the transient oscillation following fault clearing, between machine rotor angles for the most leading and most lagging generator group in the Northwest interconnected systems. Reactor impedance was varied to minimize this transient maximum angle. Curve II of Figure 6 shows that for these faults best results were obtained with reactors of about one quarter of the original impedance value (used for a single circuit fault). It will be seen that this gives somewhat better stability than with a solid bus (zero per cent reactance), with a maximum angle during swing of 115 degrees for the quarter size reactors (5.6 per cent reactance on a 100,000-kva base), compared with 136 degrees for the zero per cent reactors or solid bus. The equivalent angular difference prior to the fault was 53 degrees steady state, from prefault load studies. Curve III of Figure 6 shows that for bus faults on bus *A* at Columbia substation (see Figure 5) "best stability" is obtained with zero per cent reactances at Grand Coulee, but it will be observed that the angular swing is always less than for a fault near Grand Coulee. The significance of these angular differences as a measure of relative stability has not been fully evaluated because the maximum angular spread to which the generators can swing and recover is not shown, and it is tedious to make this determination for numerous faults in a complicated system. However, it is assumed here that a lesser angle of maximum swing indicates a greater margin of stability.

From Figure 6 it appears that approximately the same degree of stability is obtained by either a solid bus or a 12 to 13 per cent reactor, but a 6 per cent reactor gives a greater degree of stability. The reduced oscillation with optimum reactors must be evaluated as a greater margin of safety with which to meet the fault condition during a time when some other line or facility is out of service. Or system loads may materialize which produce greater unbalance in line loadings than those assumed, or greater unbalance will occur when future generating stations are added to the grid, with resultant decrease in stability margin.

Curve I of Figure 6 shows the value in kilovolt-amperes of 3-phase faults (asymmetrical component included) at Coulee plotted against size (impedance) of reactor. This shows 5,200,000-kva fault for the quarter size or 5.6 per cent reactor, and over 10,000,000 kva for the solid bus. The necessary circuit breaker rating should be greater than the fault figures shown here to allow for future system expansion, and any increase of line-to-ground fault values over 3-phase faults. It now appears that where high-speed reclosing is to be applied to the newer high interrupting capacity 230-kv circuit breakers being developed, no derating may be required for one high-speed opening and reclosing cycle.

Reactor Loading Studies

Studies were made shifting generators from bus to bus to observe the effect on line loadings. This effect was inconsequential for the 5.6 per cent reactor impedance previously found desirable for optimum stability. The power added to a bus went for the most part back through the reactors to the original busses and lines, with only a small increase in loading in the parallel lines leading from the bus in question. This is not surprising when it is realized that the value of bus reactance is the equivalent of only 35 miles of 230-kv line. From this result the conclusion may be drawn that where generation supplied to a bus differs from the natural line loadings out of that bus, the ring reactors should be capable physically of carrying the full difference. This is an important consideration also in view of the fact that the output of four or five generators will be used at Grand Coulee during the summer for irrigation pumping.

Interleaved Scheme

The study next took up the interleaved type of bussing arrangement (scheme 2). Several arrangements were investigated, but the one which gave the best results is shown in Figure 7. It will be observed, for simultaneous faults on lines occupying the same right of way, that each of the faulted lines in the interleaved scheme will be connected to a separate bus at Grand Coulee. This type of fault was more severe from a stability standpoint than when it occurred in the solid bus scheme, but slightly less severe from a circuit breaker duty standpoint than when it occurred in the five bus ring reactor scheme. These results are indicated in Figure 8.

In view of the low circuit breaker duties and passable stability characteristics of the interleaved scheme, an investigation of costs was made by the Bureau of Reclamation engineers. This indicated that the cost would probably be $500,000 less than for a five bus-ring reactor scheme. However, after further study it was abandoned because it did not allow for the condition that system loads develop in unexpected places which require flexibility to take care of such growth and to transfer power from one area to another. This flexibility is not inherent in this scheme as it is in the reactor or solid bus schemes. Another important disadvantage was that the load dispatcher would have trouble determining in advance what line loadings would occur for any given system loads and generation connected to each bus, and during emergencies when a faulty line section was cleared, even an oracle would have trouble determining how the unbalance in line loading would distribute.

Other Bussing Arrangements

A three reactor ring bus and a two reactor ring bus were investigated also. Summarizing, the stability was slightly better than for the solid bus and slightly poorer than for the five reactor ring bus. The circuit breaker duty increased rather rapidly as the number of reactors was decreased. These results are indicated also in the curves of Figure 8.

Conclusions

1. The development of a high-voltage transmission grid shows considerable overall economy in comparison with a number of relatively small isolated systems each fed from a separate bus at Grand Coulee.

2. Circuit breaker duty in the grid system is much greater than for the isolated systems, however, the additional operating flexibility which is available and the greatly increased line loadings obtainable without the loss of transient stability during emergencies, fully justify increased switchyard costs.

3. Of the various switchyard arrangements which will provide for a transmission grid the solid bus provides the greatest operating flexibility, and where high-speed clearing of faults is obtainable provides for a high degree of transient stability, but circuit breaker interrupting duty is relatively higher than for other arrangements.

4. An interleaved line scheme is the most economical and does not require exceptionally high circuit breaker duties but lacks operating flexibility and has a somewhat lower stability limit. Operation of a system with one or more lines out of service is especially difficult with the interleaved scheme.

5. A ring-type bus with sectionalizing circuit breakers provides for bus faults or for failure of equipment to clear a line fault, without losing the whole station or without losing the necessary synchronizing power between other bus sections and other parts of the transmission system.

6. When a small amount of reactance is introduced between the sections of a ring bus, a major reduction in circuit breaker duty results and a higher degree of transient stability is obtained. However, additional equipment and somewhat greater costs are involved. In addition, at Grand Coulee when a considerable part of the generation is supplying power for irrigation pumping, large transfers of power through bus reactors raises the question whether the reactor carrying capacity would always be adequate for unforeseen future operating conditions.

7. If reactors are used their benefits from the standpoint of transient stability are very high when 8-cycle circuit breakers are used but benefits decrease as the clearing time is lowered. For 3-cycle circuit breakers as used at Grand Coulee the stability benefits are relatively small.

8. In view of the foregoing considerations a five section ring bus has been selected with circuit breakers of 10,000,000-kva interrupting rating, the largest which could be developed in the relatively short time available, and with provision in the switchyard to install reactors at a future date when conditions warrant.

Discussion

W. M. Leeds (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors are to be congratulated on an excellent presentation of a very comprehensive system study and analysis of transient stability during short circuit conditions for a variety of possible bussing schemes at Grand Coulee power plant. The results of fault current calculations are of special interest to circuit breaker manufacturers, particularly if the values exceed existing standard interrupting capacity ratings. In addition to the special 10,000,000-kva 230-kv circuit breakers that will be required at Grand Coulee, what other ratings above 3,500,000 kva are indicated for nearby points on the transmission system?

With the considerable background of high power laboratory and field testing which has been accumulated in recent years, no difficulty would be anticipated in building 230-kv 3-cycle circuit breakers for either 5,000,000 or 7,500,000 kva. However, in the interest of economy, a careful survey of future requirements of the larger power systems is desirable to avoid the introduction of an unnecessary number of different circuit breaker interrupting capacity ratings.

B. V. Hoard and E. E. Helwith: The following two major points were raised by Leeds in his discussion.

1. In addition to the special 10,000,000-kva 230-kv circuit breakers at Grand Coulee, what other ratings above 3,500,000 kva are indicated for nearby points on the Bonneville Power Administration transmission system?

2. In the interest of economy it would be desirable to avoid introduction of an unnecessary number of circuit breaker interrupting ratings.

Preliminary studies indicate that for several of the intermediate stations a circuit breaker of from 5,000,000 to 7,500,000 kva will be needed within the next five to ten years on the Bonneville Power Administration system. The upper value of interrupting duty is obtained at substation locations near which another major power development is contemplated, and which will be tied into the substation. Studies indicate also that at future generating stations, several of which will have installed capacities of from 500,000 to 1,000,000 kva, the switchyards will require circuit breakers of the order of 7,500,000-kva interrupting rating.

The problem of standardizing on a number of circuit breaker ratings, which will fulfill the requirements of all of the larger power systems, but in the interests of economy avoids the introduction of an unnecessary number of different interrupting ratings, is a difficult one. Values of 3,500,000, 5,000,000, 7,000,000 and 10,000,000 kva interrupting rating or of 3,500,000, 6,000,000 and 10,000,000 kva correspond approximately to geometric ratios and may be

used. Perhaps, in view of the fact that recent tests indicate the circuit breakers rated 3,500,000 kva really are capable of interrupting up to at least 5,000,000 kva when in good operating condition that two ratings of 5,000,000 and 10,000,000 kva, respectively, should be the correct answer since both sizes are, or will be completely developed very soon.

We are not in a position to judge what the relative manufacturing costs will be, but it appears to us that if the tank, oil, bushings, and operating mechanisms for a 7,500,000 and a 10,000,000-kva circuit breaker are identical for one manufacturer, but for another manufacturer may be identical for a 2,500,000, 3,500,000, 5,000,000, and 7,500,000-kva circuit breaker, that large differences in cost for some ratings will result even though the selling prices must be commercially competitive.

From a commercial standpoint, circuit breakers of 5,000,000, 7,500,000, and 10,000,000 kva rating have already been sold by various manufacturers. Up to the present time there has been a rather large price increase in the step from 5,000,000 or 7,500,000 to 10,000,000 kva. Taking all these factors into account, it is our opinion that the ratings of 5,000,000 and 7,500,000 kva are both very definitely in the picture. On the other hand, the 10,000,000-kva circuit breaker development for Grand Coulee is not fully completed. It is our hope that future tests will show these circuit breakers will be 12,500,000 or even 15,000,000-kva circuit breakers, for a larger size than 10,000,000 kva actually is needed at Grand Coulee. For this reason, to our way of thinking, the 10,000,000 kva rating is less definite at the present time than the 5,000,000 and 7,500,000-kva values.

Measurement of Interference From Radio-Frequency Heating Equipment

GEORGE H. BROWN
FELLOW AIEE

THE continued and increasing usage of radio-frequency power generators for industrial heating processes has alerted the radio industry to the possibility of interference with existing communication channels. The Federal Communications Commission, guided by recommendations of interested manufacturers and by committees of the AIEE and the Institute of Radio Engineers, has established rules regarding electronic power generators, setting aside frequency bands for their use and establishing limits of radiated field intensity for the spurious harmonic radiations and for the cases where the generators are operated outside of the established channels. It is the purpose of this paper to describe some measurements of the fields from typical equipment and to discuss some of the pertinent factors which should be considered in connection with these measurements.

Fields from Generators Used for Dielectric Heating

Dielectric heating, the heating of inherently poor electric conductors, is usually accomplished by using generators operating at frequencies above two megacycles. In most cases, the frequency is far in excess of this figure. Induction heating of metals is generally carried out at frequencies below 0.5 megacycle. Thus the two types of heating are carried out in frequency ranges separated by the standard broadcast band. We shall first examine the case for dielectric heating equipment. The various factors which lead to spurious currents in ground wires, conduits, and oscillator frames have already been described and will not be discussed in this paper.

The extraneous currents which cause undesirable radiation may be resolved into vertical and horizontal components. In an extremely idealized case, we shall assume that these currents are concentrated at a height h above a flat ground. The measuring point, at a distance d from the source, is at a height a above the ground. The vertically-polarized field intensity at the measuring point is

$$E_V = \frac{E_D}{d}\left[\frac{2\epsilon_0(h+a)}{\sqrt{\epsilon_0-1}} + j\frac{4\pi ha}{\lambda} - j\frac{\epsilon_0^2\lambda}{\pi(\epsilon_0-1)}\right] \quad (1)$$

and the horizontally-polarized electric field intensity at the same measuring point is

$$E_H = \frac{E_D}{d}\left[\frac{2(h+a)}{\sqrt{\epsilon_0-1}} + j\frac{4\pi ha}{\lambda} - j\frac{\lambda}{\pi(\epsilon_0-1)}\right] \quad (2)$$

where

ϵ = the dielectric constant of the earth
σ = the earth conductivity (mho-centimeter)
f = frequency (cycles per second)
ϵ_0 = a complex dielectric constant $= \epsilon - j\frac{18\cdot 10^{11}\sigma}{f}$
λ = the wave length
E_D = the direct or free space field

These equations are taken directly from a paper by Charles R. Burrows[1] where in his equation 28 we substitute $2\epsilon_0/\sqrt{\epsilon_0-1}$ for his a-ib to obtain equation 1, and use $2/\sqrt{\epsilon_0-1}$ for his a-ib to obtain equation 2.

In equation 1, the middle term is the only one of importance when both h and a are large compared to the wave length. When either h or a becomes small, the first term becomes necessary, and when both h and a are small it is necessary to consider the last term. This latter term is the Sommerfeld surface term. In equation 2, the last term is generally always negligible. While a lengthy word picture could be painted of the manner in which the various terms behave, it is recommended that the interested reader substitute numerical values to get the feel of the situation.

Since the direct field E_D varies inversely as the distance d, we may rewrite equations 1 and 2 as follows.

$$E_V(\text{microvolts per meter}) = \frac{K\lambda\sqrt{W}}{d^2}\left[\frac{2\epsilon_0(h+a)/\lambda}{\sqrt{\epsilon_0-1}} + j\frac{4\pi ha}{\lambda^2} - j\frac{\epsilon_0^2}{\pi(\epsilon_0-1)}\right] \quad (3)$$

and

$$E_H(\text{microvolts per meter}) = \frac{K\lambda\sqrt{W}}{d^2}\left[\frac{2(h+a)/\lambda}{\sqrt{\epsilon_0-1}} + j\frac{4\pi ha}{\lambda^2} - j\frac{1}{\pi(\epsilon_0-1)}\right] \quad (4)$$

where W equals the watts radiated. The constant $K = 22\times 10^6$ when h, a, λ, and d are all measured in feet. When h, a, and λ are measured in feet and d is expressed in miles, the constant K is 0.789. It should be noted that in the case of radiation from an electronic generator the watts indicated in equation 3 differ from those in equation 4 since the vertically-polarized currents are not necessarily equal to the horizontally-polarized currents.

Before proceeding with further consideration of these equations, we shall examine the mode of variation of the complex dielectric constant with frequency. Let the dielectric constant of the earth ϵ be 15, with σ equal to 0.5×10^{-4} mho-centimeter. The resulting computations are shown in Table I. It may be seen that at the high frequencies, the conductivity is practically negligible, while at the low frequencies the conductivity term predominates.

As a specific example of the information which may be extracted from equations 3 and 4, we shall examine the bracketed term in each equation for a frequency of 27 megacycles and with a

Paper 48-197, recommended by the AIEE electric heating committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted March 5, 1948; made available for printing July 1, 1948.

GEORGE H. BROWN is with the Radio Corporation of America, RCA Laboratories, Princeton, N. J.

dielectric constant of 15. The results of calculation are shown in Tables II and III. Since the receiving antenna height is usually taken as 10 feet, the bracketed term of equation 3, displayed in Table II, varies from 5.59 to 7.36 as the transmitting antenna height changes from zero to 20 feet. These values substituted into equation 3 show that to produce 10 microvolts per meter at one mile the radiated power which produces the vertically-polarized field must have a value between 0.0025 and 0.00388 watt.

A similar calculation based on Table III shows that between 0.0328 watt and 5.48 watts are required to produce a horizontally-polarized field intensity of 10 microvolts per meter at one mile.

The amounts of power indicated are surprisingly small and may lead one to believe that it is a difficult task to reduce spurious radiations to the required values. To illustrate the magnitude of the field intensities encountered in practice, measurements of field intensity were carried out on a laboratory oscillator located in the RCA Laboratories. The oscillator, operating at 27 megacycles, delivered 825 watts to a wood load which was six inches square and five inches thick. The input to the plate of the oscillator was 1,725 watts. The oscillator was in a first-floor room of the brick and steel-reinforced building at the point shown in Figure 1 where the lines A and B meet. Measurements of vertically-polarized and horizontally-polarized field intensity were made at a number of locations along the two lines, using an RCA Type *301-A* field intensity meter, with the measuring antenna mounted on a tripod ten feet in height.

The resulting values of field intensity are shown in Figure 2. The line A extended across a level open field, while the line B was obstructed by a new excavation, huge mounds of earth, and an apple orchard. As one might expect, the field intensities along the line A are substantially higher. The vertically-polarized components of field intensity average four to five times higher than the corresponding horizontal components. It is interesting to note that the vertically-polarized values obtained on the line A extrapolate to 16 microvolts per meter at 1,000 feet and to the extremely low value of 0.6 microvolt per meter at one mile. It is very likely that the steel reinforcement of the building contributes to the effective shielding of this oscillator. The effect of the building structure may be illustrated by another example.

Figure 1. Plan view of the RCA Laboratories building, showing the lines along which measurements were made

A radio-frequency sewing machine[9] used for the bonding of plastic sheet was placed in the middle of a flat open field. The machine was raised about six feet above the surface of the earth, and the plate voltage adjusted to normal operating conditions. The frequency was 42.5 megacycles. With the receiving antenna ten feet above ground, measurements were made along a radial line. The results for both the vertical and horizontal components are shown in Figure 3. The upper curve shows the vertical component, which is far stronger than the horizontal component. The vertically-polarized component extrapolates to 15 microvolts per meter at one mile.

The sewing machine was next moved into the laboratory building and placed in the spot formerly occupied by the 27-megacycle oscillator. Measurements were then attempted along the line A of Figure 1. The three crosses near the bottom of Figure 3 show the values of vertically-polarized component. The horizontally-polarized components were of the same order of magnitude as the receiver noise and were not recorded. These short-range measurements, when extrapolated, show that the field intensity at one mile now reaches the unmeasurable value of 0.3 microvolt per meter.

The sewing machine was next placed in a double-shielded cage across the hall. Then it was not possible to find even a trace of signal 50 feet from the radiating source.

The Transition to Low Frequencies —the van der Pol Relation

When the frequency is below 500,000 cycles, the range commonly used for induction heating, the conductivity term in the expression for the complex dielectric constant predominates. This effect may be seen in Table I. Then equation 2

Figure 2. Measurements of field intensity radiated by the 27-megacycle oscillator

O Horizontally-polarized intensity along line A
× Vertically-polarized intensity along line B
□ Horizontally-polarized intensity along line B

becomes of no importance in comparison to equation 1 and need be considered no further. In addition, the last term in equation 1 is the only term that need be retained.

Since

$$\epsilon_0 \approx -j\frac{18\cdot 10^{11}\sigma}{f} = -j60\sigma\lambda \tag{5}$$

equation 1 becomes

$$E_V = \frac{E_D}{d}\cdot\left(\frac{60\sigma\lambda^2}{\pi}\right) \tag{6}$$

Since E_D is the direct field from the radiating source which varies inversely with the distance, we may conclude that at low frequencies the field intensity decays with distance in an inverse square relation just as did the high frequencies. Our common experience with propagation from broadcast stations does not bear out this conclusion. In fact, it is well known that waves at broadcast frequencies propagate and decay inversely with distance from some distance and then gradually approach the inverse square relationship at great distances. Doctor Burrows[1] has extended his treatment to take care of the case of vertical antennas on the surface of the earth and arrives at formulas which are in substantial agreement with experience. For our purpose of exposition of the subject, the treatment by B. van der Pol[2] seems excellent. He shows that the field intensity at the sur-

500,000,000	15-j0.18	15.

face of the earth due to a vertical radiator is

$$E_V = E_D f(\rho) \tag{7}$$

where E_D is the direct field from the radiator and from its mirror image in the earth, while $f(\rho)$ is a complicated function of a quantity ρ, which van der Pol calls the "numerical distance." It may be remarked that E_D in equation 7 is twice the value of E_D in equation 6.

The numerical distance is

$$\rho = \frac{\pi d}{60\sigma\lambda^2} \tag{8}$$

when d and λ are expressed in centimeters and σ is the conductivity of the earth, measured in mho-centimeters. For greater convenience, we may express the wave length λ in meters and the distance d in miles, with the conductivity still measured in mho-centimeters. Then

$$\rho = \frac{0.842d}{\sigma\lambda^2} \tag{9}$$

Table IV shows $f(\rho)$ as a function of ρ over a useful range. B. van der Pol also states an empirical relation for the function $f(\rho)$, that is,

$$f(\rho) = \frac{2+0.3\rho}{2+\rho+0.6\rho^2} \tag{10}$$

which agrees extremely well with the values shown in Table IV.

For large values of ρ, corresponding to great distances from the radiating source, equation 10 reduces to

$$f(\rho) = \frac{1}{2\rho} \tag{11}$$

When equations 8 and 11 are substituted into equation 7, the field intensity at a distance becomes

$$E_V = \frac{E_D}{d}\cdot\left(\frac{30\sigma\lambda^2}{\pi}\right) \tag{12}$$

Thus we find perfect agreement between equations 6 and 12, since we have already noted that E_D in the latter is twice the value of E_D in the former.

Since we shall generally be measuring field intensity from induction heating equipment at distances less than one mile at frequencies lower than 500,000 cycles per second, a substitution in equations 9 and 10 reveals that $f(\rho)$ is substantially unity. In any event, we may express the field in terms of the radiated power, W watts, as

$$E_V(\text{microvolts per meter}) = 5{,}880\,\frac{\sqrt{W}\cdot f(\rho)}{d} \tag{13}$$

where d is measured in miles.

It is of interest to note that one watt of radiated power will produce a field intensity of 5,880 microvolts per meter at one mile. To hold the field at one mile to ten microvolts per meter or less, the radiated power must not exceed three microwatts.

Radiation from Closed-Circuit Currents at Low Frequencies

In the preceding section, we found that the field intensity dropped off practically as the inverse first power of the distance when the frequency was below 500,000 cycles per second. However, this is strictly true only when the distance to the measuring point is great in comparison to the wave length. At a frequency of 300,000 cycles, the wave length is in the neighborhood of 3,000 feet. Since we desire that the radiation from industrial oscillators be less than ten microvolts per meter at one mile, we must make our measurements at much closer distances if we are to obtain reliable data to prove in the equipment.

Table II

Bracketed Term of Equation 3—Vertical Polarization
Frequency = 27 megacycles
Dielectric Constant = 15

A(feet)	= 0	5	10	15	20
a(feet) 0	5.15	5.27	5.59	6.11	6.79
5	5.27	5.37	5.73	6.28	6.91
10	5.59	5.73	6.07	6.64	7.36
15	6.11	6.25	6.64	7.25	8.04
20	6.79	6.91	7.36	8.04	8.91

The radiation from induction-heating oscillators is caused by currents flowing in closed circuits or loops, such as the frame, doors, or even the tank circuit itself.

We shall first set up the equations for the fields near a single radiating loop placed near the surface of the earth, and then show how these equations are related to actual field measurements.

Let us imagine a loop antenna of area A, and carrying a current of I amperes, standing in a vertical plane. The plane of the loop runs in a north-south direction. Then at a point which lies a distance d straight east (or west) from the loop antenna, there will exist a magnetic intensity which points east. At this point, there is no north-south component of intensity, so that another receiving loop placed at this measuring point will be subjected to a maximum piercing of flux when the plane of the receiving loop is parallel to the first loop and of course at right angles to the radial line running from the radiating source to the receiving point.

There will be no electric field intensity at this measuring point. The magnetic intensity at this measuring point we shall designate as H_p, since here the two loops must be parallel to each other to obtain maximum coupling. This magnetic intensity is given by the expression

$$H_p = \frac{IA}{\pi}\left[\frac{1}{d^3} - j\frac{k}{d^3}\right] \tag{14}$$

where $k = 2\pi/\lambda$.

The radiation resistance of the radiating loop when placed in the vertical position and close to the earth is

$$R_r = \frac{640\pi^4 A^2}{\lambda^4} = 40\cdot k^4 A^2 \tag{15}$$

and the power radiated by the loop is

$$W = 40\cdot k^4 A^2 I^2 \tag{16}$$

Substituting equation 16 in equation 14, we find

$$H_p = \frac{2}{\lambda}\cdot\sqrt{\frac{W}{40}}\left[\frac{1}{(kd)^2} - j\frac{1}{(kd)^3}\right] \tag{17}$$

Now let us imagine that we could turn our radiating loop about a vertical axis so the plane of the loop now runs in an east-west direction. Then at the measuring point straight east from the radiating loop at a distance d, the magnetic intensity will point north and the receiving loop must lie in the east-west plane in order to be pierced by the maximum flux. Thus the two loops will be coplanar, and we

Table III

Figure 3. Measurements of field intensity radiated by the radio-frequency sewing machine

• Vertically-polarized intensity, with machine in open field

O Horizontally-polarized intensity, with machine in open field

× Vertically-polarized intensity, with machine in laboratory building

shall designate the magnetic intensity of interest in this condition as H_{cp} where

$$H_{cp}=\frac{2}{\lambda}\sqrt{\frac{W}{40}}\left[\frac{1}{2}\left\{\frac{1}{kd}-\frac{1}{(kd)^3}-j\frac{1}{(kd)^2}\right\}\right] \tag{18}$$

In equation 18, the factor 1/2 has been placed inside the bracket so that the coefficient of the bracketed term will be the same as that of equation 17.

The vertical electric field at this latter measuring point is expressed by the following equation.

$$\frac{E}{120\pi}=-j\frac{2}{\lambda}\sqrt{\frac{W}{40}}\left[\frac{1}{2}\left\{\frac{1}{(kd)^3}+j\frac{1}{kd}\right\}\right] \tag{19}$$

One may observe from equations 18 and 19, provided one has been subjected to the proper stimuli, that these expressions are identical with the expressions for the electric and magnetic intensities from a short electric dipole with the roles of the electric and magnetic intensities interchanged.

Table IV. The Function $f(\rho)$ as a Function of ρ, the Numerical Distance

ρ	$f(\rho)$	ρ	$f(\rho)$
0	1	10	0.061
0.05	0.979	11	0.0539
0.10	0.958	12	0.0485
0.25	0.899	13	0.0441
0.50	0.808	14	0.0405
1	0.656	15	0.0374
2	0.440	16	0.0348
2.5	0.363	17	0.0325
3	0.303	18	0.0305
4	0.215	19	0.0287
5	0.159	20	0.0272
6	0.123	25	0.0213
7	0.098	30	0.0176
8	0.082	40	0.0130
9	0.070	50	0.0103

The space relationship of these intensities with respect to the radiating loop is shown in Figure 4.

The bracketed terms of equations 17, 18, and 19 are shown in Figure 5. Curve A is simply an inverse cube curve for comparison purposes. Curve B is the bracketed term of H_p from equation 17. It may be seen that for distances less than 1/10 wave, this relation is inverse cube of the distance and approaches inverse square as the distance becomes great. Curve C is the bracketed term of H_{cp} from equation 18. For small distances, this curve is also inverse cube with values exactly half of the corresponding values of curve B. As the distance becomes large, curve C approaches the inverse distance relation. Curve D is the bracketed term of equation 19, starting as an inverse square curve and at great distances approaching the inverse distance relation.

As the distance becomes large, equations 18 and 19 become

$$H_{cp}=\frac{E}{120\pi}=\frac{1}{2\pi d}\sqrt{\frac{W}{40}} \tag{20}$$

or

$$E=\frac{30}{d}\sqrt{\frac{W}{10}} \tag{21}$$

In equation 21, the electric intensity is expressed in volts per meter when the distance d is measured in meters. When the distance is measured in miles and the electric field intensity is expressed in microvolts per meter, the equation becomes

$$E(\text{microvolts per meter})=\frac{5{,}880\sqrt{W}}{d} \tag{22}$$

The similarity to equation 13 is apparent.

Since we have no way of telling in advance how the effective loop of radiating current is oriented in an induction-heating oscillator, we might sample the magnetic intensity at a selected measuring point. That is, we might first place our receiving loop so it points at the transmitter. The reading obtained here would be H_{cp} and would tell us something about the component of the radiating loop current which produced H_{cp}. Next, we rotate the loop until it is perpendicular to the first position. Then our radial measuring line is perpendicular to the plane of the receiving loop. A reading here will give us H_p and will then yield the remaining component of the radiating loop current.

The measurement of the magnetic intensity is quite simple. The ordinary field intensity meter which uses a loop antenna is calibrated to yield readings of electric field intensity by making use of the fact that in a radiation field, where the wave is essentially plane, the electric and magnetic field intensities are in a constant ratio. This ratio is 120π, or 377, the characteristic impedance of free space. The voltage induced in the loop is always proportional to the magnetic intensity passing through the loop. This latter proportionality is true even when the fixed ratio between the electric and magnetic intensities no longer exists. Thus we may always obtain the magnetic intensity by reading the apparent electric field intensity on the meter and dividing this value by 377. The oscillator used to obtain data to illustrate these steps was an *RCA-15B* unit, converted to operate on a frequency of 289.5 kc. The output circuit contained a transformer with a multiturn primary and a single wide copper sheet for the secondary. This sheet terminated in a single turn of copper tubing which surrounded the load. The load was a steel cylinder, 1.25 inches in diameter and approximately 4 inches long. Cooling water ran through this steel cylinder. The rate of flow and temperature rise was observed. At the time the field intensities were measured, the following conditions prevailed.

Plate voltage—8,200 volts.

Plate current—1.72 amperes.

Plate input power—14,100 watts.

Water flow through load—1.09 gallons per minute.

Temperature rise—27.2 degrees centigrade.

Power into load—7,870 watts.

The oscillator was located on the second floor of the RCA Laboratories at the position where the radial line C begins in Figure 1. The work coil was then 20

feet above ground level. Measurements were made on the line C shown in Figure 1.

The field intensity meter was an RCA Type 308-A, using a loop antenna. At all points on the measuring line, maximum signal was observed when the receiving loop antenna was turned so that the loop was perpendicular to the line C. When the loop was pointed directly at the oscillator, no reading was observable on the meter. This condition could of course be interpreted as indicating that line C was exactly perpendicular to the plane of the radiating loop, an entirely fortuitous circumstance which had nothing to do with the choice of the line C as the locale of our measuring activities.

Readings were made at many locations along the measuring line. After plotting the readings and comparing to curve B of Figure 5, it was found that the experimental points gave the best fit to the theoretical curve when exact correspondence was made at a distance of 200 feet.

The manner in which Table V was constructed may be best explained by a numerical example. At 200 feet, the apparent electric field intensity indicated by the field intensity meter was 475 microvolts per meter or 0.000475 volt per meter. This latter number divided by 377 gives 1.26×10^{-6} ampere-turns per meter for the measured H_p. This value substituted into equation 14 yields a value of 0.84 for the product IA. This means that the radiating loop was effectively one square meter in area and carried 0.84 ampere of current. Equation 16 then shows that the radiated power is 3.82×10^{-6} watts. Substitution of this power into equation 22 yields a predicted electric field intensity at one mile on a line perpendicular to line C of 1.13 microvolts per meter.

The results of measurements on line C and the corresponding calculations are shown in Table V. The first column indicates the distance from the oscillator. The second column shows the apparent electric intensities registered on the field intensity meter, while the measured values of H_p are listed in the third column. The fourth column shows the calculated values of H_p, using 0.84 for the product IA.

It is unfortunate that time and circumstances did not permit explorations on other radials. However, the author hopes that the analysis given here may guide and assist other workers interested in these problems.

Conclusion

The author has attempted to illustrate the factors which are important in interpreting the measurements of field intensity from industrial oscillators operating in the high-frequency region. The transition of the analysis from the high-frequency solution to the frequencies of interest in induction heating is made by means of van der Pol's solution of the wave equation. The near fields of radiating loops are established and correlated with measurements. Estimates of radiated power from typical industrial oscillators are made, as well as extrapolations of the data to yield field intensities one mile distant.

The smoothness of the experimental data may be attributed to the fact that the RCA Laboratories building is surrounded by open fields, with no overhead wires. The low values of field intensity are probably due to the great shielding obtained by the building construction. In built-up industrial areas, greater field may be expected where overhead wires leave the buildings and great difficulty in obtaining reliable and consistent data may be anticipated in cities.

The Measurement and Investigation of Ionization Level of Rubber Insulated Cables

R. C. GRAHAM

ASSOCIATE AIEE

Synopsis: A review is presented to show the historical development of measuring techniques and the need for practical equipment and methods to test rubber insulated cables. A new concept for equipment design is presented together with descriptions of recently developed commercial testing units suitable for such application. Design of new and novel terminal and electrode apparatus for investigation of rubber insulated cables is described, together with data obtained from laboratory and production tests.

IONIZATION* may take place when air or other gaseous medium is subjected to sufficient electrical stress to cause actual electrical discharge or corona within the medium. In order for this phenomenon to exist in a so-called "solid" dielectric it is required that air spaces or voids must exist within or on the boundaries of the dielectric. An electrical device utilizing a solid dielectric would be considered ionization-perfect for all practical purposes if all voids and air spaces were eliminated internally and externally to the device. This perfection may be approached in various degrees depending upon the mechanical, physical, chemical, and electrical nature of the device, as well as the surrounding atmospheric conditions. Within devices such as capacitors, transformers, paper insulated cables and the like, another medium such as an oil or some other fluid may be introduced to appreciably replace the ionizable air spaces. Other factors such as mechanical design are also carefully considered to eliminate or reduce voids. However, within a rubber or extruded insulated cable we must rely solely upon the selection of materials and their method of fabrication to minimize the possible air spaces that could occur between the conductor and insulation (vicinity of maximum stress under an a-c potential), at voids within the dielectric material itself, or between the insulation and any outer coverings or medium. Therefore, one of the main objectives of this investigation was to study ways and means of properly evaluating this characteristic of rubber and extruded insulated cables and the subsequent ways and means of improvement.

The deleterious effects of ionization are well known and have been rigorously studied by other investigators. As early as 1893 Steinmetz[1] presented a paper on the subject followed by many others.[2–6] In spite of limited measuring equipment available to the earliest investigators these men established the basic principles of field theory, corona formation, and made some good predictions as to the probable nature of the phenomenon of ionization. The art of making cables was far enough advanced so that the application of higher voltages in cables paralleled the use of higher voltage on overhead transmission lines. It is not surprising therefore that in 1898, R. F. Fessenden performed experiments which showed the danger of air bubbles in solid insulation. It was soon discovered that ionization of air spaces within solid dielectrics caused a deterioration of organic insulation.

If the electrical stress is sufficient to cause ionization in voids or air spaces, failure of the insulation may occur without excessive general temperature rise through localized overheating due to increased power loss in the void, or to progressive local deterioration due to discharges. Ionization of air causes the formation of small quantities of ozone and oxides of nitrogen. The nitrogen oxides may chemically attack cellulose materials and certain metals whereas the presence of ozone leads to rapid physical deterioration of insulating materials and in the case of nonozone-resistant rubber insulations, causes corona cuts or checking similar in appearance to that produced by strong sunlight. Because a wide band of frequencies is produced by corona discharge, serious radio or television interference may be caused by ionization, either by direct radiation or by conduction through the circuit itself. Thus, it is important to the manufacturer as well as the user to know the effects of and to be able to determine the point at which ionization originates in any circuit component.

Until 1930 the measurement of ionization point was made indirectly by means of its effect on the dielectric loss or power factor of insulation. This was measured at first by special wattmeters and later by high-voltage power-factor bridges. Since high-frequency disturbances are associated with ionization and since the progress of electronics led to the development of sensitive amplifiers and detec-

* Ionization is a fundamental process which is found in various forms in many branches of electrical engineering. The word is used here to describe that ionization which may occur in a dielectric subjected to electrical stress. More specifically, the expression "ionization point" is used herein as a synonym for other commonly used but similar meaning terms such as "corona or corona-ionization level," "corona extinction or ignition voltage," and "critical ionization potential." When this expression is used in the text, reference will be made to extinction voltage unless otherwise explained.

Paper 48-198, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 10, 1948; made available for printing July 20, 1948.

The authors wish to acknowledge assistance of the laboratory staff of Rome Cable Corporation and the engineers of Rome Cable and Thermionic Engineering Corporation for their encouragement and advice.

Figure 1. Ionization bridge circuit

tors, the next step was to use these disturbances as a measure of ionization point. This was done by several investigators between 1930 and 1945.[7–11] However, most of the equipment developed to date was individually designed and constructed for laboratory purposes only. These apparatus varied in degree of sensitivity and accuracy, required special sample preparation, and were limited to measurement of relatively small or low capacity specimens. This presented the need for development of a satisfactory commercial instrument with a high degree of accuracy and sensitivity which would be safely and simply used for regular production measurements as well as in the laboratory and in the field.

New Concepts in the Measurement of Ionization

It is generally believed that ionization is the result of bombardment of molecules by particles of atomic or subatomic dimensions. It is believed that the bombarding particles are accelerated by the application of high-voltage gradient. This fundamental bombardment concept has been shown and used repeatedly in the study of atomic physics. Ionization results when the bombardment causes electrons to become freed from their parent molecule. Regardless of the exact mechanism of release, each freed electron induces a charge on the electrodes near it. The magnitude of the charge is 1.6×10^{-19} coulombs in the rationalized meter-kilogram-second system of units.

In a capacitor or short length of cable, the release of electrons will charge the plates or conductors in a very short time to a voltage which is determined from

$$V=\frac{Q}{C} \tag{1}$$

In the equation, Q is the charge in coulombs which is equivalent to the number of electrons released, multiplied by the charge on each electron as given before. The capacitance C is that of the capacitor or cable. An assumption is made that the plates of the capacitor or cable are isolated by an inductance from the circuit which completes a path from positive to negative plate. If this is so, the capacitor becomes completely charged before an appreciable charge leaks off through the external circuit. Even up to a length of several thousand feet, the time required for charging wavefront to traverse a cable is only a few microseconds. A cable connected through an inductance to an external circuit and charged instantaneously by release of electrons behaves from that point on as though it had received a step voltage. The response in the network can be determined by transient analysis.

The use of a bridge circuit for balancing external disturbances out of the ionization detector is well known. It is also known that complete balance is never obtained. This latter is attributed to the fact that all known high voltage bridges give a satisfactory balance only over a band of frequencies which is narrow compared to the bandwidth covered by ionization voltages. In order to understand the limitations of this circuit, it is desirable to analyze the response of a bridge to signals of the type previously described.

A Schering bridge, balanced at one frequency, is balanced at all frequencies, if the standard and the unknown capacitors both have the same power factor. This is equivalent, in the terminology of transient analysis, to saying that both the unknown and the standard have the same time constant if the bridge balances to an impulse or step signal. This equality between time constants is a necessary condition for bridge balance when the applied signal contains impulses, rectangular pulses, or step voltages having a steep front. At first glance, this would seem to rule out the bridge as far as eliminating external transients is concerned, since the unknown will, in general, have a different time constant than the standard. However, a transient study of the circuit provides information which leads to a more efficient use of the bridge circuit.

In Figure 1, a circuit is shown which has a different power factor or time constant in the standard (C_3) from that of the unknown (C_4). To solve this circuit most expeditiously, assume that an infinite impedance detector will be used. It is then permissible to consider each branch of the bridge separately and compare the voltages across C_1 and C_3. Consider the left hand branch of the bridge with a step voltage applied and solve for the voltage across C_1.

$$e_1=e_0\,\frac{C_3}{C_1+C_3}\;\epsilon^{\frac{-t}{R_1(C_1+C_3)}} \tag{2}$$

In equation 2, e_1 represents the voltage across C_1, e_0 represents a step voltage of amplitude e_0, t represents time after the application of e_0 and the remaining letters represent the circuit constants. The value of e_1 plotted against time for a representative bridge is shown on Figure 2.

Next consider the right hand side of the bridge with the same step voltage applied. In this case, there will be a steady-state response which can be ignored because the measuring network and the detector will greatly attenuate any d-c signal.

Figure 2 (left). Response of an ionization bridge

Figure 3. Filter ionization detector

Figure 4 (left). Basic circuit of self-contained ionization measuring equipment

Figure 5. Recently developed ionization detector (front view)

The transient response is seen as follows.

$$e_3 = e_0 \frac{C_4}{C_3+C_4} \, \epsilon^{\frac{-t}{R_3(C_3+C_4)}} \times \left[1-\left(\frac{C_3+C_4}{C_4}\right)\left(\frac{R_4}{R_3+R_4}\right)\right] \epsilon^{\frac{-t}{R_4(C_3+C_4)}} \quad (3)$$

In equation 3, e_3 represents the voltage across C_3. It will be seen that this is given by the product of two exponentials, one of which is similar in form to equation 2. This first exponential can be made exactly the same as equation 2 by maintaining the following equalities.

$$\frac{C_1}{C_3} = \frac{C_2}{C_4} \quad (4)$$

$$R_1C_1 = R_3C_3 \quad (5)$$

If this is done

$$e_3 = e_1 \left[1-\left(\frac{C_3+C_4}{C_4}\right)\left(\frac{R_3}{R_3+R_4}\right)\right] \times \epsilon^{\frac{-t}{R_4(C_3+C_4)}} \quad (6)$$

Formally, in such a bridge, the quantity $(C_3+C_4)/C_4$ will not exceed 100 while the quantity R_3/R_3+R_4 will easily be less than 0.0001. Equation 6 may thus be simplified giving as a close approximation

$$e_3 = e_1 \, \epsilon^{\frac{-t}{R_4(C_3+C_4)}} \quad (7)$$

It will be found that e_3 as given in equation 7 is equal to e_1 (equation 2) where $t=0$ and $t=\infty$. Both voltages are shown in Figure 2 and also their difference e_x.

From equations 4 and 5 it is apparent that the balance which results in the voltage e_x is obtained by making the capacitance balance normally as in conventional bridges. The time constant balance is made by making the time constant of C_1 equal that of C_3 regardless of the difference between time constants in standard and unknown (C_3 and C_4). It has been assumed that the standard has nearly zero power factor and power factor of the unknown is not greater than 20 per cent.

The response of the bridge to pulses originating within the bridge is more difficult to compute algebraically and was abandoned in favor of numerical analysis of a suitable bridge designed on the basis of the previous equations. The numerical analysis showed that the response to a step voltage applied in series with the unknown capacitor is a steep front exponential like e_1 and e_2 of Figure 2. Its peak amplitude is about 30 times as great as that obtained when the same step voltage is applied externally to the balanced bridge. Furthermore, the response to external signal is much flatter. For a fairly close graphical comparison of the responses to the same signal applied in the two different places, see e_1 and e_x of Figure 2.

In the actual circuits if there is ionization external to the bridge it will generally be of much greater magnitude than the first stages of ionization within the bridge. The 30-to-1 advantage described before is easily overbalanced by excessive ionization external to the bridge. It is possible to make use of the flatness of the response to external ionization in further discriminating between it and the desired response. If the signal is passed through an electronic differentiating amplifier or, RC peaker, there will be an attenuation of flat pulses with respect to steep pulses. By using a bridge circuit designed according to the principles discussed before and using a differentiating detector, it is expected that rejection ratios of several 1,000 to 1 may be obtained.

Within the last 12 years, there has appeared a different form of ionization detection circuit. This circuit uses a filter to discriminate between ionization signals originating within the unknown capacitor and those originating externally. Early models were built so that the sheath of the unknown capacitor or cable was required to be insulated from ground. This is not an inherent requirement. Recent equipment permits grounding the sample. This feature, combined with the absence of any balancing procedure, is sufficient cause for interest in the circuit.

The simplest form of the filter circuit is shown in Figure 3. The secondary of the high voltage transformer is represented by its distributed capacitance, C_1. The capacitance C_3 represents the sample. A loading capacitor C_r is also supplied and in series with it is the pick up coil L_s with its distributed capacity C_L. An r-f reactor L_F is connected in the high voltage lead

Figure 6. Recently developed ionization detector (rear view)

Figure 7. Ionization detector (front view)

This instrument used for production and laboratory tests described in this paper

between the transformer and the loading capacitor. The distributed capacity of this coil C_F is important. The response in L_e to a transient applied at either C_1 or C_0 depends on the ratio of the capacities in the circuit during the initial instant. If C_F is large compared with the other capacities in the circuit, there will be coupling between the two meshes regardless of the value of inductor L_F.

The ratio of the responses at L_e to equal step voltages applied at C_1 and C_0 is easily computed using the ratio of capacitances and the circuit of Figure 3. It is

$$\frac{e_{L1}}{e_{L0}} = C_0\left(\frac{1}{C_1}+\frac{1}{C_F}\right) \tag{8}$$

where e_{L1} represents the response to external signal applied at C_1 and e_{L0} represents response to the ionization signal in the unknown capacitor C_0. It will be seen that the rejection ratio depends on the size of the unknown capacitor and is more favorable as the capacity increases.

The capacitance of a 10-foot length of typical shielded cable is about 600 micromicrofarads. If C_F is made as small as 20, and C_1 equal to 200 micromicrofarads, the available rejection ratio is 33. This is satisfactory only when external disturbances and any appreciable ionization are eliminated in the high voltage transformer or other circuit components. Where such ionization is present, a rejection ratio of 10,000 or more would be desirable. This could be obtained if the length of cable tested was in the order of a few thousand feet. To test such a length of cable requires a transformer with adequate kilovolt-ampere capacity. Other methods of increasing the rejection ratio have been tried, but none of them have been successful enough to warrant further consideration. The outstanding result of this analysis is to show that the high voltage supply and other components in the filter-type ionization-detection circuits must be corona free. It is obvious that the loading capacitor and all connections to the transformer and sample must also be corona free.

It is suggested here that the sensitivity of ionization detectors of the electronic type might be defined as the double amplitude of a square wave applied to the specimen terminals which will produce a pulse 1-inch high on the screen of the oscilloscope used as an indicator. A method of applying this calibrating square wave while the set is operating follows. Connect a capacitor of approximately 0.002 microfarad to the high-voltage test terminal. This capacitor should be corona free to at least 5-kv. In series with it connect a capacitor of at least 2 microfarads. Apply the square wave across this latter. From the amplitude of the square wave, the ratio between the two capacitors and the internal circuit of the detector it is possible to compute the square wave amplitude at the test terminal.

Modern Methods and Equipment Used for Detection of Ionization in the Range 0–35 Kv

Schering Bridge Circuits

Most existing ionization detectors use the Schering bridge circuit. This alone is not capable of balancing out all extraneous impulses, except in the few cases where the standard and the sample capacitors are nearly identical in capacity and power factor. For this reason, experimenters working with a wide range of sample sizes have had to make their high voltage supply comparatively free from ionization.

A further precaution taken by some[12] is that of using a variable standard capacitor, a feature which is expensive to build and not easy to arrange for safe operation. The size of such a capacitor is limited, which, in turn limits the size and length of cable that can be tested. Other disadvantages of the bridge method are the need for balancing each sample, and the fact that the sample sheath cannot be at ground potential, such as would be required for production tests in grounded water tanks.

However, for laboratory setups on small samples, the bridge method is probably as good as any other. Where existing transformers must be used or where, for other reasons, some ionization external to the bridge is expected, the bridge is the only method that can be used. Where a bridge is used, the analysis of bridge per-

Figure 10 (left). Probe electrode assembly

Shows cable under test

Figure 11. Removable probe electrodes of various sizes

formance as described previously will be a useful guide.

Because of the lack of inductors in the bridge circuit ionization appears as a unidirectional pulse if a broad-band amplifier is used. Ionization in the standard capacitor will then appear in the opposite direction from that in the sample. This fact has been used to discriminate between ionization in the body of the sample and ionization in the terminations. A guard ring on each end of the sample was connected to the return of the standard. Thus any ionization in the guard circuit was indicated as part of the standard ionization. Another advantage of the bridge circuit lies in its simplicity from a computation point of view. This gives an advantage in basic measurements of ionization. The bridge circuit can be set up for operation at a point remote from the high-voltage area. This is only true when the standard capacitor is fixed. If so, it offers a strong argument from a safety point of view. This, however, is more important where test voltages are greater than 35-kv, in which case the use of the bridge circuit is universal.

Filter Circuits—Development of Commercial Equipment

Until quite recently, manufacturers and other investigators interested in ionization testing have had to design and construct their own equipment. This gave rise to a lack of uniformity, standard procedures, and results which have limited any widespread practical applications. This experience has indicated that a need existed for certain definite ionization instruments for laboratory, field, and especially production measurements.

It was decided that the most desirable arrangement for commercial equipment for cable and similar component testing should involve the filter circuit since it is the easiest to operate and maintain. Moreover, it can be used to measure an extremely wide range of capacitance without requirement of a balancing operation and permits the cable sheath to be connected to ground. Cables without conducting sheaths or shields can be tested in the same grounded water tanks used in all cable factories to perform the conventional voltage and insulation resistance

Figure 12. Ionization-free terminal

tests on rubber insulated conductors. Since the testing unit itself could be compactly designed to be semiportable and entirely self-contained, the high voltage supply and associated components must be free of ionization and, therefore, the rejection ratio need not be high. It has been found that testing with such equipment can be as rapid and safe as making dielectric tests with a portable dielectric tester. A circuit diagram showing the essential parts of these ionization detectors is given in Figure 4.

Figures 5 and 6 show the front and rear view of a recently developed ionization tester based upon these conditions. This portable equipment was designed mainly for general laboratory applications and is complete within itself. The unit is corona free to 30,000 volts and contains a 5-kva 60-cycle high-voltage transformer. The loading capacitor is an oil-filled paper type such as used for surge generators and is rated at 70,000 volts at 60 cycles continuously. This capacitor has a value of 0.003 microfarad. Voltage is measured directly using a capacitor divider and a vacuum tube voltmeter. An induction regulator is used to control the voltage. This model includes a broadband amplifier which shows up the pulse nature of ionization quite clearly. Since there seems to be good reason for considering ionization as a step voltage it seemed logical to calibrate the amplifier in terms of a similar signal. The sensitivity of this instrument measured by the previously proposed method is 0.1 volt. This was found to be more than ample.

Figures 7 and 8 show the front and rear view of an ionization test instrument specially designed for production tests on rubber insulated and other extruded cable types and for general purpose laboratory tests on cable samples and components. This is the instrument which was used to obtain all of the measurements to be described later. In most respects it is similar to the unit previously described but is corona free to a rated maximum of 15,000 volts and a higher capacity of 10-kva in

order to provide the required charging current for long or full factory reel lengths of cable. The loading capacitor is rated at 33,000 volts and has a capacitance of 0.005 microfarad. The pick-up coil is a 25-millihenry inductor. Voltage regulation is by means of an autotransformer and voltage measurement is accomplished by a primary voltmeter. The controls, including a foot-operated switch, are so arranged that it is impossible to energize the high-voltage transformer until the regulating autotransformer has been returned to zero. This prevents the accidental and sudden application of full voltage to the sample or cable under test. At the rear of the unit, in a protected location, is an oil-filled bakelite tube which is used as a high-voltage terminal (Figure 9). A mercury pool located in the electrode at the base of the tube provides means of making spark-free contact. This is the conventional method of connecting samples to this type of ionization detector and does not require more than ordinary care in the preparation of samples. It is adaptable to a wide range of cable sizes and constructions and can be readily disconnected.

It is possible with additional external terminal equipment to test short sections of a long cable length without cutting the piece. In order to do this a probe electrode assembly was designed as shown in Figure 10 with different removable probe electrodes as shown in Figure 11. The cable to be tested must be unshielded and is passed through the close fitting tubular

electrode. These electrodes are about three inches long although tests have indicated that a longer electrode may have some advantage. The electrode is maintained at the test voltage while the conductor of the test cable is connected to ground. To prevent induced charge on the surface of the sample, grounding rollers are placed at each side of the probe. This auxiliary electrode assembly has been found to have excellent laboratory applications in detecting the exact localized area of low ionization and in studying the cause and effect of these areas on other characteristics.

Indicators

The indicators used for ionization are varied. Early equipment took advantage of the sensitivity of head phones and ionization was identified by its peculiar frying sound. Later, amplifiers were used in conjunction with a rectifier voltmeter or a peak reading voltmeter which gave a good indication and offered a better measure of ionization intensity. Since the initial signal is a steep wavefront and the response depends on the nature of the circuit as well as the characteristics of the indicator, it is difficult to find any means of calibrating two differently designed instruments so that their results can be correlated. The best solution has been to use an oscilloscope which provides a measure of the peak amplitude of pulses. It shows the wave shape so that different kinds of response can be separated and it can show the relative position on the exciting wave at which the pulse is formed. It combines all the good features of the indicators previously listed and has none of the bad features. The only thing lacking in an oscilloscope indicator is a means of integrating or counting pulses, but at the present stage of ionization measurement an integrating device is not essential since the objective is to find the ionization ignition and extinction voltages.

For certain laboratory applications it may be desirable to add a pulse counter to the oscilloscope in order to obtain an indication of the total quantity of ionization. For some applications a recorder has been used.[13]

Investigation of Ionization Level of Rubber Insulated Cables

The evolution of the testing of solid dielectrics has been a history of improvement of electrical apparatus and methods of analysis. Through this evolutionary method a great number of valuable and informative tests have been developed for the evaluation of the elements of insulated cable, and to establish the critical limits of operation. These include some full-reel length tests such as insulation resistance, capacitance, power factor, and voltage test; and additional short length tests for specific insulations such as rubber, to evaluate the dielectric material itself with respect to dielectric strength, moisture resistance, ozone resistance, and physical properties. These tests do not entirely evaluate a cable made of these elements.

Within the structure it is possible that at some point ionizable voids (air

spaces) may exist between the strand and insulation, within the insulation or between the insulation and shield or sheath. These defects may be due to manufacturing errors or to displacement after manufacture because of flexing or other mechanical distortion.

During service, ionization may take place with extremely destructive effects. The result is attributed to corona cutting, oxidation, weak spots in the insulation or just low dielectric strength; since the evidence necessary for a critical analysis is generally destroyed, or the mechanism of breakdown has created evidence common to any of these causes.

Such tests as have been developed for the detection of these types of discontinuity or nonhomogeneity in the insulation are destructive and therefore confined to the short lengths mentioned before. There appears to be a need for a method to detect such voids by nondestructive means which may be applied to any length of cable, with or without a grounded sheath. The ionization detecting equipment previously described has been developed to fulfill this need, and was used to obtain the information given in the following section.

Cable Preparation and Measurement

In order to accurately determine the voltage at which ionization occurs within insulated cables, the method of terminating the cable is of prime importance. The operator must be assured that the cable ends are free of surface leakage in the form of discharges since they are readily picked up through the detector circuit at voltages considerably lower than the ionization under measurement. The method of termination should be readily prepared and simple in form, especially if it is to be adapted to production testing where full-reel lengths are immersed in test tanks or shielded with some form of conductive sheath. This section describes the development and subsequent use of two distinct types of terminations that have been proven successful for use in laboratory and production testing, in that they are simple, convenient to use and corona-free at the test voltages encountered.

Figure 9 shows the first method of termination especially adapted to shielded cables, which consists of an oil-filled bakelite tube with a mercury cup at the bottom for the high-voltage connection. The cable ends are prepared by removing the conductive shield for a distance of a foot, forming a smooth rounded surface at the edge, and then immersing them in the oil-filled terminal so that the conductors come in contact with the mercury electrode. Unshielded cables immersed in test tanks may also be tested using this termination, by simply sliding a snug-fitting copper shielding braid over the exposed ends and treating it as a shielded cable. This type of terminal has been found to be corona-free up to 35 kv and is constructed as an integral part of the measuring equipment.

Figure 12 shows the second method of termination especially adapted to production testing of unshielded finished cables and insulated conductors immersed in test tanks. The premolded, semiconducting Neoprene terminal has an exponential flare which eliminates concentrated stress at the water line, and is filled with a high-dielectric constant fluid such as glycerine which absorbs any formation of corona energy due to end leakage. The flexibility and elasticity of the terminal permits a snug fit around the cable insulation which holds it in proper position and prevents leakage of the glycerine. Terminals can be made up in several sizes to accommodate the cables under test. Shielded cables may also be tested using this method by terminating the conductive sheath at the base of the cone, and applying tightly wrapped metallic foil over the end of the conductive sheath extending over the end of the preformed cone. Check measurements made with the Schering bridge show that this method is satisfactory up to 15 kv and possibly higher, which will be determined upon further investigation.

Figure 16. X-Ray photograph indicating loose insulation

Once the selected terminal is applied, the operator only has to raise the test voltage until the first signs of high-frequency oscillations appear on the oscilloscope trace (Figures 13 and 14) indicating the inception point. The voltage is then gradually decreased until all signs of corona disappear, which is the extinction point and occurs at a voltage about ten per cent lower due to the reduced energy necessary to maintain the ionization occurring within the cable. Ionization values given in this paper represent the extinction voltage, since cables stressed at this level in operation would only require a slight surge to initiate the ionization. The information presented in this section was obtained on nominally rated 5-kv oil-base rubber insulated cables conforming to American Society for Testing Materials specification *D574* and will be referred to hereafter by conductor size and construction.

Ionization Detector versus Power Factor Bridge

Sufficient data have been obtained on various cable sizes and lengths ranging from 2,000-foot reels to 15-foot samples, whereby the accuracy of the ionization detector using the terminations developed was checked against the standard 60-cycle Schering bridge method as shown in Tables I and II. The fact that the detector directly measures the lowest point of ionization level of the cable under test, as against the Schering bridge method which approaches an over-all ionization level, is of great importance since the low value is associated with the weakest part of the cable. The latter statement was verified by the measurement of two 15-foot number 4/0 American wire gauge (AWG) stranded cables whose ionization levels were 3.5 and 6.0 kv as obtained by the Schering bridge method. The two cables were then measured simultaneously, the resulting ionization level being 5.4 kv. This is accounted for by the limited sensitivity of the Schering bridge in measuring very small over-all power factor increases due to ionization of localized air voids or spaces.

Breakdown Voltage Versus Ionization Point

It has been the general opinion that internal ionization level of rubber insulated power cables bears some relation to the breakdown voltage since voids, porous insulation or loose insulations are detrimental factors, as explained previously and could influence both values in the same manner. As a starting point in this investigation cable samples were limited to those nominally rated at 5 kv, shielded and unshielded, with as complete a coverage of conductor sizes as was possible. The ionization level was measured on each sample prior to breakdown, which was conducted on 15-foot lengths, properly terminated, by applying 200 average volts per mil for five minutes and then increasing the voltage in 5-kv steps at 5-minute intervals. Six of the samples were subjected to 200 volts per mil for a week to determine what effects this would have on the ionization level and corresponding breakdown.

The data presented in this section, although preliminary inform in that they only represent 5-kv wall thicknesses, indicate a definite pattern as shown in Figure 15, from which a relationship between ionization level and breakdown voltage could be obtained. However, no attempt will be made to expand this relationship at the present time, since it is felt that additional data now being compiled with respect to various wall thicknesses will be more substantiating. As can be seen in Figure 15 and Table III, the cables subjected to 200 volts per mil (average) for a week showed no appreciable change in ionization level or breakdown voltage. Additional data with respect to longer periods of voltage application are also under way.

A1	5.2	3.5
A2	5.5	3.3
A3	5.2	3.3
A4	5.0	3.0
B1	5.4	5.4

Ionization Point Versus Temperature

The question arises as to whether or not the measurement of the ionization level of a cable at room temperature is indicative of its operation under load, inasmuch as the operating temperatures are usually in the order of 75 degrees centigrade. Table IV indicates no appreciable change in ionization level for a cable using conductor adhesives, and a drop from 6.8 kv to 5.0 kv for a cable without adhesive. Since some high-voltage cables are manufactured with conductor adhesives, the measurement of ionization level at room temperature on such cables is considered justifiable. It is further significant that the ionization level at room temperature should exceed the operating voltage if any safety factor is desired at the operating temperature.

Probe Measurements

As was mentioned previously, it is possible to confine the ionization measurements to short sections of a long unshielded cable, through the use of a close fitting tubular probe about three inches in length as shown in Figures 10 and 11. This is a significant development in view of the fact that it provides a nondestructive means of locating voids or air spaces within a long cable length which can then be analyzed by dissection or X ray to determine its exact nature. The information thus gained can be used in producing improved cable.

Data were obtained on a full reel of number 8 AWG stranded cable showing its ionization point to be 3 kv, which indicated poor cable construction somewhere within the 1000-foot length, since similar reels tested at the same time had an ionization level of 10 kv. By passing the cable through the probe with the applied voltage set at 7.5 kv, no ionization was recorded until a section of cable was located at which point the ionization level was 3.0 kv. X-ray photographs and visual examination indicated that the conductor adhesive was lacking and the insulation loose at this point as shown in Figure 16. Since this could not be detected with the standard nondestructive methods it establishes the importance of this analysis.

Use of Ionization Detector for Analysis of Factory Repairs in Cables

Besides being able to locate low ionization areas in long cable lengths, the probe apparatus proved advantageous in analyzing cable repairs. By passing the repaired cable section through the probe and measuring the ionization of the insulation patch and the cable on either side, it is possible to locate void forma-

Table VIII. Typical Factory Test Results on Nominally Rated 5-Kilovolt Cables

Size	Description	Length Feet	Ionization Level Kilovolts
350,000 circular mils, stranded	Unshielded	1060	5.2
		1030	5.5
		1030	5.3

*Rejected due to loose insulation.

tions that might have occurred during the taping or molding operation. Table V illustrates this, in that the patches whose ionization level was equal to that of the cable were satisfactory, as indicated by breakdown voltage and visual analysis. The patches whose ionization was below that of the cable were not satisfactory due to void formations.

Such a method of evaluating patches lends itself readily to production testing, since it is nondestructive and serves as an indicator of acceptability. The probe electrode could be of the split-type so that it would not be necessary to pass the entire cable length through the probe. A similar method of analysis using properly designed portable detection equipment might well prove advantageous in application to field splices and repairs.

Use of Conductor Adhesives for Rubber Insulated Power Cables

Use of conductor adhesives has been suggested as a means of maintaining a high ionization level for rubber insulated cables with stranded conductors. Insulating rubber cements applied over the conductor prior to the insulation fills the strand interstices and, in addition, insures a strong bond which prevents loosening of the insulation due to flexing when undergoing further processing or handling during installation. An investigation was conducted whereby full-reel lengths of 350,000 circular mils cables were manufactured without any conductor adhesives and measured with the detector while immersed in test tanks prior to the application of a lead sheath. The respective ionization levels were measured again after the lead sheath had been applied. The results of this test shown in Table VI definitely indicate a drop from the initial 5-kv ionization point to the final 3-kv ionization point which is believed due to the further process handling combined with the lack of conductor adhesive. On the other hand, an accompanying reel of number 4/0 AWG stranded cable manufactured with conductor adhesive showed no decrease in ionization level.

Further data showing the need for conductor adhesives were obtained on two reels of two conductor number 8 AWG solid cable, where one reel of cable was manufactured with conductor adhesive and the other without. Table VII shows the ionization level of each reel to be 6 kv and 3 kv respectively.

The value of conductor adhesives becomes more apparent with respect to ionization at the elevated operating temperatures of the cable, where the expansion characteristics tend to loosen the insulation from the conductors as shown in Table IV.

Conductor Shielding for Rubber Insulated Power Cables

Use of conductor shielding in the form of semiconducting tapes or compounds is another possible means of maintaining a high ionization level for rubber insulated cables and is successfully being incorporated in the manufacture of cables at the present time. A sample of number 4/0 AWG stranded cable which had a semiconducting cloth tape applied over the strand prior to insulating showed improved dielectric strength in the order of 37 per cent and an ionization level which was increased approximately 1.5 kv when compared with conventional conductor adhesive. This is significant in that it indicates the possibility of similar beneficial effects as obtained with the use of conductor adhesives, besides permitting free stripping qualities of the insulation. A further study of the use of conductor shielding is in order for cables wherein free stripping properties of the insulation can be tolerated.

Production Tests on Full Reel Lengths

Typical factory test results of ionization level obtained on full-reel lengths of nominally rated 5-kv cables using the ionization detector are shown in Table VIII. This not only indicates the possible use of the detector for production testing, but also shows that cables can be manufactured so that their ionization level is above their nominal rating. Its use is advantageous also in that low-ionization levels usually indicate faulty cable construction which probably would not be detected under standard factory test procedures, especially if the bad section of cable were well within the reel length.

All unshielded cables including Neoprene-sheathed type were tested in water tanks. All lead sheathed cables were tested with the sheath grounded.

While all of the foregoing investigation was confined to rubber insulated cables, considerable data have also been obtained upon polyethylene thermoplastic insulated types of power and communication cables. The expansion and contraction characteristics of polyethylene are so appreciable that very special extrusion and handling conditions must be observed if a void-free product is to be obtained. Since the ionization of voids in polyethylene cause rapidly deteriorating effects[14] it is already recognized that the ionization detector must be used as a production control test on any polyethylene cable intended to operate at voltages in excess of 1,000 if satisfactory performance is to be obtained. Investigations relating to this subject are being continued and will be reported at a future date.

Inasmuch as it has been shown that the ionization detector can be used as a practical nondestructive production or laboratory test on rubber insulated cables, and since the effects of ionization are deleterious, it would seem that such a test would be advantageous to the manufacturer as well as the cable user. The significance of ionization tests is not limited in its importance to cables. The very fact that the transformers, capacitors, connectors, and other circuit components used in the ionization detector unit itself required special treatments and, in some cases, redesign in order to obtain corona-free performance within their nominally rated voltage range, indicates a similar need for rigid investigation.

Conclusions

1. New concepts of equipment design together with the development of commercial testing units has been described, and the value of the ionization detector as a nondestructive test for cables and cable repairs is analyzed.

2. A relationship between ionization level and dielectric strength has been shown to

exist for a definite insulation and cable construction. Methods of overcoming the deleterious effects of ionization have been discussed indicating their advantages.

3. Corona-free terminal designs have been developed and adapted to production tests of ionization level on full-reel lengths of insulated cables.

Discussion

Theodore F. Stipp (Department of Water and Power, Los Angeles, Calif.): It appears that the authors have developed testing equipment and methods that should prove extremely useful, both in production testing and in improving cable design and manufacturing methods.

We have never felt that the common commercial method of testing for ionization was of much use in determining the presence of voids in rubber or synthetic insulations; so in purchasing cable of that type, we have not asked for ionization tests on our 5-kv cable, and have specified that our 34.5-kv cable be made with a semiconducting tape over the conductor and another semiconducting tape over the insulation, which, we note that the authors state, materially increases the dielectric strength and ionization level.

The statement of the authors as to the need of investigation into ionization and corona in transformers and other equipment was proved to us in 1941 when our test laboratories, using connections as given G. E. Quinn[1] and some modifications, ran some tests in an effort to determine the voltage level at which bushings and insulators would give radio interference. Due to interference caused by the high-voltage transformer, it was possible to run tests only on small pin-type insulators up to 10 kv, so these tests were not carried any further.

1. A Method for Detecting the Ionization Point on Electrical Apparatus, G. E. Quinn. AIEE Transactions, volume 59, December 1940, pages 680–2 and 1232.

C. E. Betzer (Commonwealth Edison Company, Chicago, Ill.): The authors show that with modern methods of manufacture 5,000-volt rubber-insulated cables can be made free from corona at rated voltage. That is an improvement as such cables made ten years ago had lower corona starting voltages. At that time, tape and saturated cotton braid were commonly used over the insulation and much of the cable was unshielded. In tests at the University of Illinois of samples resting on metal plates, the corona-starting voltages were generally from 2,400 to 3,000 volts between conductor and plate. Those same cables with the braids removed had corona-starting voltages from 3,000 to 4,400 volts. Now the use of braids has been generally discontinued and jackets of synthetic rubber are used for outer coverings. By the use of adhesive or conducting rubber between the insulation and conductor and tight shielding or conducting rubber over the insulation, corona can be eliminated.

The application of lead sheath over rubber insulation is shown to decrease markedly the ionization level, in some cases. This suggests that handling and aging might have a similar effect. The tests at the University of Illinois included some tests of cables that had been bent, some that had been stored for two years, and some that had been in service for from five to seven years. Such handling and aging was found to produce no consistent change in the ionization level.

Some of the rubber compounds have been able to withstand moderate amounts of corona in service, but, as suggested by the authors, some of the new synthetics which have other attractive properties are more susceptible to damage by corona. It is gratifying to note that the authors are working on this problem and will report on it in a subsequent AIEE paper.

E. W. Greenfield (Anaconda Wire and Cable Company, Hastings-on-Hudson, New York): The paper on ionization determination in rubber-insulated cables by Graham, Duffy and Foster is a valuable contribution on the use of this type of equipment. It was not very long ago that the writer, presenting a paper on the use of corona detectors for high-voltage paper cable,[1] was told by a few cable makers that such apparatus was of little value. I am glad to say, however, that the majority of serious investigators in this field have come to look upon corona detection as of paramount importance in the study and production of high-grade insulated cables.

The following discussion will be limited to comments on the paper in the order of the text as presented.

In their first paragraph, the authors inform us that ionization can take place only where a gaseous phase is present. They overlook the fact that ionization may take place in both liquids and solids in the complete absence of voids or gas pockets. The ionization of neutral molecules by such free electrons as are present in a liquid, is the factor which produces the electron avalanches leading to break down. Indeed, the corona detector is a valuable instrument for the study of electron discharge voltages in liquid insulators.

The transient analysis of the Schering bridge, as given by the authors, is interesting. However, it is not quite clear how this applies to the steady-state conditions existing during bridge manipulation. Using the well-known steady-state bridge-circuit theory, the same conclusions, as arrived at by the authors, are readily apparent. Equation 5 in the paper can be satisfied only when the power factor of the standard is the same as that of the sample. Otherwise, an in-phase component of current will appear across the detector terminals. Also in the transient equations the sample is represented as a simple R-C circuit. Actually, the parallel resistance is absorptive in nature, and in general, the simple time constants arising from normal polarization are not obeyed.

With regard to the filter ionization detector, it is not clear how the system rejects the large 60-cycle component, unless this is the function of the wide-band video amplifier tuned to band-pass only frequencies in the megacycle range. If so, why was it found necessary to eliminate the lower frequencies? More information on this point would be appreciated. Also, have the authors made any frequency analysis of the types of discharge present in rubber cables?

With regard to the sensitivity calibration of ionization detectors, I am in agreement with the authors that a uniform calibration scheme would be of value. At our laboratories, we use a 1,000-cycle sine wave, since the filters are adjusted to pass everything from 1,000 cycles up. Also on the matter of calibration, in order to avoid errors due to applied-voltage wave-shape, it has been found desirable to specify peak applied voltage rather than the rms voltage.

Under the discussion of Schering bridge ionization detectors, the authors indicate that such devices could not be adapted to measure earthed cable, and are thereby severely limited in usefulness for testing production and installed cables. I would like to point out that two methods are available for using a Schering bridge corona detector upon earthed cable. The first method involves inverting the bridge and placing

the balancing resistors, condensers, and detector at high potential. The second method and the only one in use in our laboratory is to use the bridge in its conventional form and shield the high-tension leads completely. Such shielding may be connected to the junction of the bridge resistor arms as is also the shield of the high-voltage transformer. All such shielding requires low-voltage insulation from ground.

The use of the probe electrodes, as described by the authors, is very interesting. I am wondering how corona discharge between the probe and the surface of the cable under test can be eliminated, however.

With regard to the coronaless terminal shown by the authors in Figure 12, it is of interest to learn how the exponential flare was arrived at. The purpose of the slope is, of course, to control the stress by maintaining a uniform longitudinal value. We have long utilized a flare which follows a log-log curve, the equation of which is readily derivable. The use of glycerine in the terminal would appear to be a poor selection since this material is completely miscible with water in all proportions and is generally found to give much trouble.

With regards to the statement on ionization volume, I am in accord with the authors in their belief that an integrated pulse count would be highly desirable. We are of the opinion that a vacuum-tube type of wattmeter of sufficiently high sensitivity could be used to integrate the current pulses. This together with a high-impedance voltmeter should provide a measure of both intensity of discharge and the volume of such present.

In the use of the terminals described for production cable testing, are there any checks made to determine the corona point of the high-voltage system and terminals themselves? The bridge method permits ready elimination of system corona and evaluation of terminal discharges. It is essential to design these so that no discharges are present to the top usable limit of the equipment.

Under the section "Ionization Detector versus Power Factor Bridge," it is not clear just how the comparisons were arrived at. It would appear that the authors attempt to check their corona-point determinations by means of power factor versus voltage curves. If so, the two may give decidedly different values, particularly in the presence of moisture.

The data presented on rubber cables during factory tests are very interesting and prove conclusively the value of this tool in searching out weak spots. It is noted that the general level of corona extinction was on the order of 6 to 8 kv for this type of cable. It is of interest to compare these values with corona-extinction points we obtain on similar size cable using our type ABP (butyl-polyethylene) 5-kv insulated cables.[2] Our values range from 9 kv to 16.8 kv for cable with 4/0 American wire gauge copper and 10/64 inch insulation. In many cases for 12/64 inch ABP-insulated cable, we obtain no measurable corona current at voltages up to 20 kv.

2. Type ABP High-Voltage Insulation—An Improved Thermosetting Compound, L. F. Hickernell. Given before the 41st Meeting of the Transmission and Distribution Committee, Edison Electric Institute, 1946. Reprinted by Anaconda Copper Company, New York, N. Y., Publication *C-63*, October 1947.

R. C. Graham, E. K. Duffy, and W. P. Foster: Regarding Greenfield's comments the transient analysis is more apropos to corona discharges which are inherently transient. The use of a simple R-C circuit was decided upon in order to show, generally, what happens. In any exact mathematical analysis of response during corona discharge, it will be necessary to consider the transient analysis of the complex R-C circuit which exactly represents the performance of the cable. The filter ionization detector rejects the 60-cycle component by making use of the wide difference in impedance at 60 cycles between the loading capacitor and the radio-frequency coil. Further rejection is obtained by tuning the amplifier.

The authors stated that the Schering bridge ionization detector has the disadvantage of not being adaptable to the measurement of earthed cables, such as would be encountered for production tests in grounded water tanks. It is recognized that methods are available for overcoming this disadvantage in laboratory equipment. However, where laboratory tests are concerned, it is a simple matter to insulate the cable under test from ground.

The primary purpose of the probe electrode is to detect the exact localized area of low ionization within unshielded cables, or to determine the relative values among several similar cables by setting the applied voltage at a predetermined value which is considerably below that which would represent the ionization voltage between the electrode and cable; full reel lengths of cable can be checked by this nondestructive test. No attempt is made to determine the true ionization level of the cable as this can be readily accomplished on the entire length as described in the text.

As Greenfield points out, the exponential flare incorporated in the ionization-free terminal has been in use for a long time and is readily derived. However, the unique method of incorporating an elastic semiconducting material which adapts itself to a wide range of a different size cable is described for the first time in this paper, since there has not been any practical method of terminating cable lengths immersed in grounded water tanks for testing, on a production basis. The use of glycerine to absorb any formation of corona energy was resorted to mainly because of its high dielectric constant and the fact that it is miscible with water which permits the cable ends to be readily cleaned.

The general level of corona extinction was in the order of 6 to 8 kv, based upon factory production tests of insulated rubber cable. On laboratory measurements involving short lengths of similar type oil-base insulated cables, values of the order referred to for type ABP insulation have been obtained.

Results of Tests Carried Out at the 500-Kv Experimental Station of Chevilly (France), Especially on Corona Behavior of Bundle Conductors

FRANCOIS CAHEN
MEMBER AIEE

THE 500-kv experimental station of Chevilly, near Paris, France, has been built with a view to making a close study of the behavior of the lines to be used when building up the French 400-kv system. Present economic conditions in France do not favor the use of copper conductors. In consequence, two solutions have been considered for the equipment of these lines.

1. Utilization of large diameter (1.58 to 1.97 inches) expanded aluminum-cable-steel reinforced (ACSR) conductors.

2. The use of a bundle of two conventional ACSR (1.04-inch-diameter) conductors, the total cross section of which is equal to the economic section.

To facilitate at the opportune moment the rapid layout of a 400-kv system, while meeting at the same time the needs for extension of the existing 230-kv system, the new high-capacity transmission lines of the latter are being designed in the form of double-circuit 230-kv 6-conductor lines laid on a horizontal plane and convertible into single circuit 400-kv lines. The Le Breuil-Chevilly line was designed along these lines. This line is 252 miles long and is equipped with six standard 0.638-square inch ACSR conductors. This line was put in operation in December 1946 (Figure 1).

If single large diameter conductors are utilized, when this line is converted into a single 400-kv line, the six conductors now in use will have to be taken down. If, however, the bundle technique is adopted, the conversion of the line will be obtained through a mere regrouping of the six conductors now in operation into three bundles of two conductors each. This second method is not only quicker than the first but offers the advantage of utilizing only standard cables.

The station of Chevilly was built mainly for carrying out experiments and comparisons on the two methods as regards corona losses and radio influence under all kinds of atmospheric conditions; for selecting the optimum operating voltage; for determining, when utilizing bundle conductors, the most favorable spacing between conductors as conditioned by the corona effect, the sticking of conductors under the effect of the wind, electrodynamic stresses due to short circuits, their disposition either on a vertical and horizontal plane, and finally, for studying insulators and line hardware.

Description of Experimental Station

The station has been erected close to the 230-kv Chevilly substation located in the suburbs of Paris, 300 feet above sea level.

It consists of a single-line span the length of which, 1,640 feet, is equal to the mean span of the convertible Le Breuil-Chevilly line. The end towers of the span are conventional suspension towers (Figures 2, 3, 4). The phase spacing is 47.5 feet. The line is anchored to the ground at both ends by means of guys linked to the line conductors by double insulator strings. Each suspension string carries 24 insulators (diameter 11.2 inches, spacing 6 inches). Suspension and dead-end strings are provided with grading rings. Two ground wires, located 46 feet above the conductors, may be, either insulated or grounded. Wooden trestles have been erected below the three phases in order to keep the conductors off the ground when being laid down and thus avoid their getting soiled.

A bundle is composed of two standard 0.638 square inch ACSR conductors (aluminum cross section 0.505 square inch, outer diameter 1.04 inch). They are supported by clamps fixed on an adjustable link attached to the lower insulator fitting. Conductors may be laid either side-by-side at the same level (horizontal layout) or one above the other (vertical layout). "Bakelised" wooden spacers may be placed between the conductors at one or several points of the span.

Figure 1. Standard double circuit 230-kv suspension tower

Paper 48-199, recommended by the AIEE transmission and distribution committee and approved by the technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 8, 1948; made available for printing June 30, 1948.

FRANCOIS CAHEN is manager, systems studies and research division, Electricite de France, Paris, France.

Figure 2. Standard single circuit 400—500 kv suspension tower

Three kinds of expanded ACSR conductors will be tested with diameters of 1.57, 1.77, and 1.97 inches.

The supply station (Figures 5 and 6) includes three 106-kva, single-phase transformers; the 11-kv delta-connected low-voltage windings are provided with no-load tap changers which make it possible to obtain a no-load high-voltage range of from 178 to 289 kv (phase-to-neutral voltage) or from 308 to 500 kv (phase-to-phase voltage) in 64 steps.

The high-voltage windings are star connected, the neutral being solidly grounded.

It was deemed advisable to give the line the length of a single span so as to facilitate the systematical study of meteorological conditions and make the replacement of conductors easier. The output of the transformers has been limited to that which was strictly necessary to keep the line energized. This allows the reduction of transformer losses and also the checking of some high-voltage measurements by the help of low-voltage measurements. In this way the station was set up with a maximum of economy not inconsistent with the securing of accurate results.

Besides the main experimental line, another single-phase, insulated line, 36 feet long, has been pulled along the axis of a grounded cylindrical lattice 79 inches in diameter. This feature gives the possibility of rapid tests on short lengths of conductors and of a close examination of corona effect phenomena.

The voltage supply of this line is such that the conductors are subjected to the same surface gradient as those of the main lines; atmospheric precipitations get through the lattice, which in addition can be sprayed with artificial rain.

Finally, in order to study the influence of air density on the corona effect, two more experimental stations have been built one at Chevilly, close to the 500-kv line, and the other in the Alps at Alpe d'Huez, 6,000 feet above sea level.

These two stations, identical in design (Figures 7 and 8), include a 330-foot span of 230-kv, single-phase line fed by a potential transformer at a 133-kv phase-to-ground voltage. To obtain, under single-phase operation, a surface gradient equal to that of a normal 3-phase line, conductors having a very small diameter (ASCR 0.23 square inch, outer diameter 0.62 inch) have been utilized. In addition to this, another grounded line identical to the first has been strung parallel to the first one. This second line makes possible the comparison of the weathering of live conductors with that of dead conductors.

Program of Tests

The tests which were initiated in December 1946 and which have been going on since without interruption, have been carried out according to the following plan:

Corona Losses

Bundle Conductors:

Effect of voltage on corona losses; corona curves.

Influence of weathering of conductors on losses.

Influence of atmospheric and weather conditions on losses and uninterrupted recording of losses under constant voltage.

Influence of spacing of bundle conductors on losses.

Comparison between vertical and horizontal position of conductors in bundle.

Figure 3. Standard single circuit 400—500 kv suspension tower

Figure 4. 500-kv experimental line with a span length of 1,640 feet

Influence of ground wires.

Comparison of losses on each of the three phases among themselves; comparison of losses in single, 2 or 3-phase supply.

Measurement of insulator string losses.

Expanded Conductors:

Same tests as indicated before except with regard to the influence of spacing and position of bundle conductors.

Influence of Air Density (230-Kv Experimental Stations):

Effect of voltage on corona losses; corona curves.

Weathering of conductors.

Influence of atmospheric and weather conditions on losses and uninterrupted recording under constant voltage.

Study of Sticking of Bundle Conductors Under the Effect of the Wind and Short Circuit Currents

Horizontal and vertical lay-out.

Radio Disturbances

Variation of disturbing field with: voltage; atmospheric conditions; type of conductors; and distance from the line.

The measurements are made in the vicinity of the 500-kv, experimental line, the 230-kv single-phase, experimental line and several 230-kv lines of the French system now in operation.

Results of Corona Losses Measurements

The processes utilized for the measurement of corona losses, as well as a part of the results of tests carried out in 1947, were described in three previous reports.[1,2,3]

The sum of the results secured up to May 1, 1948 will be recapitulated and commented hereafter.

Figure 5. The 500-kv test station of Chevilly

Figure 8. The 230-kv test station of Alpe d'Huez, 5,900 feet above sea-level

General Scheme For the Carrying Out of Tests

Two processes were applied:

—Plotting, by points, the curves of losses versus voltage. This process is practicable only in dry weather. In bad weather, especially in the case of rain or snow, losses are generally too unstable to make for an accurate plotting of curves. Even in dry weather, it is necessary to act very quickly as losses vary sometimes within an hour's time. This is due to the influence of temperature changes on air density and height of conductors above the ground and the effect of dust deposit on conductors in relation with the direction and speed of wind.

Curves of losses versus voltage are used mainly to study the weathering of cables, the influence of air density, the comparisons between various spacings (bundle), different diameters of conductors (expanded cables) and studies on the electric field.

Uninterrupted recording of losses under constant voltage. These recordings are utilized mainly to study the influence of weather conditions (rain, snow, fog, sleet) upon losses and to make comparisons between conductors of different spacings and diameters when subjected to these conditions.

These tests are supplemented by illustrations of brushes, which were photographed at night (Figures 9 and 10).

It would be useful to carry out all these measurements under a 3-phase supply, the three phases being provided with the same conductors, so as to work under the same conditions as for industrial operation.

But this process entails long delaying periods, owing to the length of time necessary for the weathering of conductors (from three to six months) and the large number of dispositions and types of conductors that would have to be tested. Moreover when two different layouts have been successively tested, it is impossible to make sure that the weather conditions they were subjected to were the same in both cases.

Figure 6. The 500-kv test station of Chevilly showing single-phase transformer and capacitive divider for voltage measurements

Figure 7. The 230-kv test station of Chevilly, 300 feet above sea-level

It has therefore been found preferable for comparisons between both types and dispositions of conductors to proceed as follows:

The outer phase, 3, equipped with two conductors in horizontal layout with a spacing of 16 inches, is selected as a basis and suffers no alteration all through the test period. Changes in the disposition (bundle) or changes of conductors (expanded) are carried out on the other two phases, 1 and 2.

In order to compare the different dispositions of bundles, the changes are carried out in succession on the other outer phase 1. The outer phases 3 and 1 alone are alive, the median phase 2 being grounded.

For the comparison between different types of expanded cables, these cables are laid both on median phase 2 and on the extreme phase 1, the reference phase 3 continuing with a bundle equipment. The three phases are energized.

But this implies that for tests 1 it may be possible to obtain results under a 2-phase supply which would be equally valid under 3-phase supply. This also supposes that for tests 2 it may be possible to separate the losses due to each one of the phases and deduct therefrom the value of 3-phase losses that would have occurred should the equipment have been homogeneous.

Interpretation of Tests

Transposition of Loss Measurements From the Single and Double Phase to the 3-phase Supply:

This transposition is made easy by assuming that for a given conductor (or system of conductors), under given meteorological conditions, the value of losses is related to the value of the theo-

retical surface gradient. In the case of a single conductor, the calculation of the gradient is easily made by applying electrostatic laws; it proceeds directly from the value of capacitance factors which can be both calculated and measured. In the case of a bundle of conductors, it is necessary, as will be shown later on, to take into account an equivalent surface gradient, which can also be calculated from the capacitance factors.

Should this assumption prove correct, the plotting of the curve of losses versus voltage, carried out, for instance, under a single-phase supply on one of the phases of the line, makes possible the drawing of the corresponding curve under 3 phase supply. In fact, by dividing the abscissae of the single-phase curve by the ratio of theoretical gradients under 3- and single-phase operation, the ratio being calculated to the value of capacitance factors, the new curve of losses is obtained for 3-phase operation. The loss curves for the other two phases are determined in a similar way if allowance is made for the fact that the two outer phases are theoretically submitted to the same gradient while the central one is submitted to a higher gradient.

Table II gives as an illustration of the foregoing, the coefficients to be applied at Chevilly, in the case of a bundle of two conductors, with a spacing of 16 inches at a supposed temperature of 20 degrees centigrade.

Experimentation has particularly consisted in checking, in the shortest time possible, the curves of losses of the line under single- and 3-phase supply and in comparing, for each phase, the losses measured under each different supply. This implies that the problem of the separation of losses under 3-phase operation studied further has been solved.

It has been possible to observe that the coincidence of the plotted curves of loss versus surface gradient was satisfactory without being perfect. That depends, first of all, on the difficulty of experimentation arising from the instability of loss curves even in dry weather. Moreover, below the critical voltage, curves are often ill defined while above this voltage the capacitance factors (consequently the theoretical gradients) are modified by space charges as shown by the curves on Figure 11. These were checked during fair weather and rain on one of the 230-kv experimental lines.

A much better coincidence of curves is obtained by utilizing the measured capacitance currents as abscissae instead of the gradients, as shown on Figure 12. The near coincidence of single and 3 phase curves will be noticed for each one of the phases 2 and 3, both equipped with bundle conductors. The difference between phase 2 and phase 3 curves is caused by the fact that the second one is more weathered than the first.

From the sum of researches carried out, the conclusion may be drawn that the error on the gradients resulting from the use of theoretical switchover factors does not exceed 4 per cent.

Division of Losses:

The reading of the individual wattmeters of the three phases does not give an accurate indication of losses pertaining to each particular phase, even after making the corrections rendered necessary by the reactive power flow between the phases. In reality, the watt component of a phase current is the amount of watt current which flows into the ground plus the watt current exchanged between the phases, which depends both on the value of the losses of the phase under survey and the losses of the other phases. The division of losses may be effected by assuming that the loss angle has the same value in all directions which is the same as assuming the proportionality of loss currents and capacitive currents. Experimentation has shown this assumption to be but roughly approximate. However,

Table I

	Sticking Current, Amperes				Unsticking Current, Amperes			
	Computed		Measured		Computed		Measured	
	First Method	Second Method	Minimum	Maximum	First Method	Second Method	Minimum	Maximum

Distance, inches 16	1,520	1,820	1,650	1,730	1,100	1,320	1,180	1,250
Distance, inches 20	1,900	2,270	2,150	2,240	1,305	1,560	1,420	

as the error likely to be made concerns only a corrective term, this method of dividing the losses has been found sufficiently accurate.

Case of Bundle Conductors: Influence of Their Spacing and Layout

Theoretical Study:

The theoretical study of the surface field of a bundle of two smooth conductors has been made in a previous report.[1]

Supposing two insulated conductors brought to the same potential V_0 in relation with the ground (Figure 13).

Let:

r = conductor radius
D = distance between conductors' axes
h = average height of conductors above the ground.

The capacity per unit length of the line in relation with the ground is:

$$c = \frac{1}{2\ln\frac{2h}{\sqrt{rD}}}$$

The mean surface gradient is:

$$E_m = \frac{V_0 c}{r}$$

The potential gradient at a point M of one conductor's surface is:

$$E = E_m\left(1 + \frac{2r}{D}\cos\alpha\right) \qquad (1)$$

This gradient is minimum in B:

$$E_B = E_m\left(1 - \frac{2r}{D}\right)$$

It is maximum in A:

$$E_A = E_m\left(1 + \frac{2r}{D}\right)$$

For $r = 0.52$ inch; $D = 16$ inches, the extreme relative variation is $\doteq 6.6$ per 100.

On the other hand, the calculation shows that the presence of two adjacent phases, under 3-phase operation, does not modify the law of variation of the surface gradient, owing to the great distance between phases. Its only effect is to increase the load on each one of the conductors, and consequently the capacity per unit length c and the mean gradient E_m.

If the spacing of the conductors increases, the minimum and mean gradients are constantly on the increase and the maximum gradient goes through a minimum which in the case of the Chevilly line occurs at a spacing of 11.4 inches (Figure 14).

Corona losses are closely related to the value of the theoretical surface gradient (at least, in so far as the latter does not exceed by too great a margin, the critical voltage above which space charges modify the outline of the field). In the case of bundle conductors, however, the surface gradient not being constant at the periphery of the conductors as shown in equation (1), the law of loss variations versus conductor spacing is not that which determines the variation of the maximum gradient. This was rendered manifest by the tests.

The theoretical study also shows that surface gradients are the same whether conductors are laid horizontally or vertically.

Practical Results:

The experimental survey was carried out in the manner described before. It included the checkings by points of loss curves versus voltage and recordings under constant voltage in the rain.

Losses vary but very little when the spacing of conductors lies between 8 and 16 inches; the minimum of losses in good and bad weather corresponds to a spacing of approximately 8 inches. The law of loss variations has been observed in this case to be the same, as if on the surface of each conductor a constant gradient prevailed equal to the mean of the maximum and mean gradients represented by the equation:

$$E_e = E_m\left(1 + \frac{r}{D}\right)$$

The variation of this equivalent gradient versus spacing is figured by the dotted curve on Figure 14. It is minimum for a spacing of 7.5 inches which tallies with experimental results.

Beyond 16 inches, losses keep on increasing more and more rapidly. At 32 inches they are at least four times higher than at 16 inches.

Losses are the same regardless of the weather, whether conductors are laid horizontally or vertically.

Weathering of Conductors—Losses by Weather

The conductors are pulled without undergoing any preliminary cleaning process, as would be done when building a line, but special precautions are taken while they are being pulled. The well-known phenomenon of weathering is then observed, and manifests itself in a progressive reduction of losses. This

Figure 11. 230-kv test station

Effect of voltage variation on losses and ground capacity

Figure 13. A single phase line with a bundle of two conductors

reduction is important only if the conductor is kept alive.

Weathering has been observed (Figure 15) on a bundle of two conductors as well as on a line with single 1.77-inch conductor and on the two 230-kv installations of Chevilly and Alpe d'Huez.

The value of 3-phase losses on weathered conductors during dry weather and no fog, for a bundle of two conductors with a spacing of 16 inches is as follows:

400 kv—less than	0.8 kilowatt per mile
420 kv—	1.1 kilowatt per mile
440 kv—	1.6 kilowatt per mile
460 kv—	2.7 kilowatt per mile

For the first 1.77-inch expanded cables, which are being experimented upon, losses, after three months' weathering, are about ten times as high as those of the bundle. According to theoretical calculations however they should be about the same.

Influence of Ground Wires

The presence of ground wires increases theoretical surface gradients by one to two per cent, which is confirmed by loss measurements.

Losses Due to Insulator Strings

Measurements of insulator string losses carried out during all kinds of weather have shown that these losses always remain very small in comparison with the corona losses of conductors. Total losses due to the insulator strings of a line operated at 400 kv (1,640 feet span, two strings per phase) calculated from experimental results should be about 10 per cent of conductor corona losses.

Corona Losses by Bad Weather

Numerous recordings of constant voltage losses have been carried out on the experimental line under the most varied atmospherical condition (rain, snow, fog, sleet) and have emphasized a well-known phenomenon, the increase in corona losses which at times becomes considerable.

The plotting of loss versus voltage curves, although very difficult to carry out accurately during bad weather, shows the relative increase in losses to be more important below than above the critical voltage. For very high gradients, losses in dry and bad weather have a tendency to become somewhat similar.

In the course of recordings carried out in all weather from January 1, 1947 to April 30, 1948, the highest peak losses were recorded in the spring of 1947 at the beginning of heavy rain storms. In the case of rain storms a very swift rise in losses is observed at the beginning followed by a peak lasting only a few minutes. Afterwards losses decrease and keep on being pretty irregular. When the shower is over, losses decrease during the drying process according to a law of exponential shape. Figure 16 illustrates some typical recordings obtained on bundle conductors (with a spacing of 16 inches) and on an expanded cable 1.77 inches in diameter. The peaks of losses recorded at the time of snowfalls are not so high as in the case of heavy rainfalls. This has been observed both at Chevilly and at the high altitude station. The same thing occurs during foggy weather.

Figure 15. Corona losses versus phase-to-ground voltage during good weather under single-phase supply showing influence of weathering and difference between bundle conductors (16 inches spacing, lower curves) and expanded conductor (1.77 inch diameter, upper curves)

The highest peak losses recorded in the above mentioned period, corresponding to 16 months' experimentation on bundle conductors (16 inches spacing), brought back to 3-phase supply were as follows:

397 kv—105 kilowatts per mile
413 kv—130 kilowatts per mile

With an expanded cable 1.77 inch in diameter (three months' experimentation), losses in bad weather are about double those of bundle conductors (16 inches spacing).

A test has been made to correlate the energy wasted in losses under a shower and the height of rainwater recorded by the pluviometer. This correlation is not bad as can be seen on Figure 17. It shows an average loss of 14.5 kilowatt-hours per mile and per millimeter of rainwater for the center phase equipped with two bundle conductors with a spacing of 16 inches, under a voltage corresponding to 3-phase 400-kv. The corresponding 3-phase loss would be 40 kilowatt-hours

per mile and per millimeter of rainwater at 400 kv.

Influence of Air Density

Study of air density δ influence on corona losses has been systematically carried out at the 500-kv Chevilly station. This study has shown as a first approximation[1] that the voltage corresponding to a given value of losses varies in direct proportion to δ. But this verification has not seemed sufficient on account of the slight variation of the density in relation to meteorological conditions (temperature, pressure under constant altitude). That is why, with the object of building high altitude lines, the two single-phase 230-kv stations described before have been erected.

The tests, carried out in these stations, included both the plotting of loss versus voltage curves and uninterrupted recordings made under constant voltage, by means of automatic recorders. Figure 18 shows, on the one hand, loss curves in dry weather as checked in both stations without any air density correction and, on the other hand, the same curves corrected by the value of air density by applying the law of Peterson.[4] This law states, that if the critical voltage is not deviated from by too great a margin, the voltage corresponding to a given value of losses varies in direct proportion to $\delta^{2/3}$. Under these conditions the curve concordance is excellent. The confirmation of Peterson's formula by the tests is all the more interesting as the difference between air densities is greater:

$$\frac{\delta \text{ Alpe d'Huez}}{\delta \text{ Chevilly}} = 0.8$$

Recordings during rain have shown, that under an equal voltage, the increase in losses due to high altitude is far less important than in dry weather.

If these results are applied to the 400-kv line, the values of losses versus altitude (bundle conductors 16 inches spacing) as shown in Table III are obtained.

The study of radio disturbances shows that disturbances caused by the 400-kv line are, at a voltage of 400 kv, of about the same importance as disturbances observed in the vicinity of the 230-kv lines recently put in operation on the system. They keep on increasing with the voltage, but not so quickly, however, as losses. At 440 kv they are higher by 80 to 90 per 100 than at 400 kv.

Mechanical Actions Between Bundle Conductors

One of the important problems arising from the use of bundle conductors is the closing up of conductors under the effect of high winds and short circuits. An accidental contact between conductors is not dangerous but it is necessary to avoid their sticking together, that is, their remaining in contact along an important length owing to an aerodynamic effect in case of high wind, or to electrodynamic attraction stresses likely to persist after elimination of a short circuit on the system, not directly affecting the involved line (load transfer after elimination of a parallel line affected by a fault). A protracted sticking would in fact bring about an important increase in corona losses and radio disturbances and risk damaging the conductors.

The detailed, theoretical study of closing up phenomena following a short circuit, that is, sticking and parting in the case of two bundle conductors laid horizontally has been together with the re-

Table III

12	2	1
16	2	0
20	1	0
24	1	0

sults made of tests carried out for the verification of its validity. The theoretical study with regard to bundle conductors laid vertically has also been made and its correction confirmed by a series of quite recent tests.

For the computation of sticking and parting currents, it is necessary to take into account electrostatic repulsion stresses and electrodynamic attraction stresses. When the line is on no-load, only the former occur and cause the spacing between conductors to increase. When the line is loaded, the spacing decreases and the balance of the stresses, expressed by the parallelism of the conductors, is reached when the line is operated at its surge impedance load. With a short circuit, the attraction stresses alone occur or, at least, are largely in excess.

Table I gives some of the results obtained when supplying conductors with direct current of variable intensity and shows, opposite, the results of the theoretical study.

Fair agreement between experimental and calculated results points out the possibility of taking the latter as a basis for finding out the minimum number of spacers required to avoid a continuous sticking of conductors after elimination of the short circuit. This has been obtained by fixing at 1,300 amperes (900 megawatts at 400 kv) the intensity likely to be carried by the line after elimination of a short circuit on a parallel line. The minimum number of spacers required per 1,640 feet span are shown in Table IV.

Recordings of closing-up of conductors by high wind have shown that with horizontal layout, two spacers at least for a spacing of 16 inches and one spacer for 24 inches were required to avoid sticking. Vertically, closeups are practically nil; no spacer is required for spacings of 16 and 20 inches.

General Conclusions

A general survey of the theoretical studies and tests, which have been carried out for the last 18 months, leads to the positive conclusion that it is possible to operate a line of the same type as the experimental line of Chevilly under a phase-to-phase voltage, equal at least to 400 kv, 50 cycles.

Should the technique of two bundle conductors be adopted, the right spacing will be 16 to 20 inches, with which corona losses are but little over the minimum corresponding to the conductors utilized (1.04 inch diameter) and for which the minimum number of spacers per 1,640-foot span does not exceed two, for conductors bundled in a horizontal layout. When the bundle is laid vertically no spacer is required which makes this layout more advantageous. It means, however, slightly higher towers and consequently an increase in the cost of erection of the line.

With an operating voltage of 400 kv, losses during good weather are lower than 0.8 kw per mile, and are comparable to those on existing 230-kv lines. They are therefore much lower in comparison with the transmitted power. Losses during bad weather are much higher than in fair weather. If allowance is made for the alternate spells of dry and wet weather, the total amount of power lost through corona losses is perfectly admissible.

Based on observations made at Chevilly on a survey of the route covered by the le Breuil-Chevilly line (250 miles long) and on observations of the rainfall and the differences in altitude along this same route, it is estimated that the average corona losses per annum would be 4 kw per mile, if this line were operated under a mean voltage of 400 kv. Under 440 kv losses would be two to three times higher which still would be admissible.

In reality the limitation of the operating voltage will depend on radio disturbances. It is not at all certain that it may be possible in this respect to go much over 400 kv, at least not without increasing the diameter of conductors at certain points.

With regard to expanded conductors, experimentation has not been going on long enough to be able to draw definite conclusions on the subject. All types of cables have not yet been tested. For the time being it appears that expanded conductors seem to give higher losses than the bundle conductors, especially during dry weather.

Discussion

M. Temoshok (General Electric Company, Schenectady, N.Y.): An important contribution of this paper is the correlation between the variable surface voltage gradient of the bundle conductors and the corona loss; that is, the use of the equivalent constant gradient as being equal to the average of the mean and maximum gradients. In establishing such a criterion, it should be noted that when the ratio of spacing between bundle conductors to conductor diameters becomes less than five, the approximate equations used in the paper for the solving of the surface voltage gradients become an error. This error arises because the field produced by one conductor in the vicinity of the other is no longer parallel, an assumption of the approximate equation.

Mention is made of experimental losses in good weather being ten times greater for the single-conductor expanded-cable of 1.77 inches in diameter than for the bundle conductors of 1.04 inches diameter. This in itself is an astonishing result, as the surface voltage gradient of the single conductor is appreciably less than that of each conductor of the bundle conductors. Since the surface voltage gradients of the bundle conductors were illustrated, it would have been of interest to have indicated the surface voltage gradient of the single conductor used in the comparisons.

All results dealing with surface voltage gradients have been checked closely by results of similar calculations made by the writer, with one exception. The values of Figure 14 of *g*, the surface voltage gradient kv per centimeter per phase kv, seem to be lower than expected for a 3-phase calculation. As the "Theoretical Study" discussion presents only the equations for surface voltage gradients of two conductors at the same potential above ground, it would appear that Figure 14 would be the result of calculations using these equations, and does not represent an actual 3-phase case.

P. L. Bellaschi (Consulting Engineer, Sharon, Pa.): In recent years, considerable experimental work has been conducted in Europe, directed to the development of a-c power transmission at extra-high voltages. The corona studies at Chevilly, France, in particular have been outstanding in this connection, and we are

fortunate in having the paper by François Cahen. Likewise, there have been noteworthy contributions in this field in Sweden and in Switzerland. In fact, the entire subject of power transmission at extra-high voltages was a topic of extensive and constructive discussion at the recent International Conference on Large High-Voltage Electric Systems held in Paris, June 24 to July 3, 1948.

In Sweden, a 380-kv line has been projected from the Harspranget Waterfalls to the south, the center of consumption, some 960 kilometers in length. Here, too, bundle conductors have received preference over the expanded or hollow conductors. To minimize corona loss and radio noise, steel-reinforced aluminum cable conductors, 1.26 inches in diameter, spaced 18 inches apart in a 2-bundle arrangement and disposed horizontally have been selected. The larger conductors have been justified in addition for economic reasons, that is, capitalization of copper losses and so forth. Apparently, operating conditions prevailing in that country, such as sleet and ice formation, have been among the factors influencing the selection of the horizontal arrangement.

In view of the preference apparently being given to the vertical arrangement, as indicated in the paper, it may be in order to pose the question whether sleet, ice formation, and similar difficulties are likely to be a matter of practical concern with this arrangement for the conditions likely to be encountered on the proposed 400-kv lines in France.

Another point which presents itself is the matter of relative advantage of bundle and expanded or hollow conductors from the corona standpoint. According to Figure 15 of the paper, bundle conductors are at an advantage over the expanded or hollow conductors. However, this comparison does not appear to be a final one, as it would seem some of the expanded and hollow conductors tested at Chevilly could well stand further improvements from a manufacturing standpoint, thus minimizing some of the irregularities present in the original conductors tested. Additional tests on improved conductors should be helpful in clarifying this point. This apparently is the intent of the program at Chevilly, as intimated in the paper.

One can state quite objectively that the contributions by Cahen and his associates mark an important and outstanding milestone in the field of high-voltage corona studies. In the light of the findings at Chevilly, France, and elsewhere, one can feel with definite assurance that the major questions and technical difficulties which presented themselves to the minds of transmission engineers several years ago in regard to the corona problem at extra-high voltages are being rapidly overcome in a masterly and practical manner. Additional experimental data are, of course, desirable in order to clarify certain remaining questions. A final decision on some of these points probably cannot be reached other than by actual experience which, in view of the developments in course in Sweden and France, should not be too long forthcoming.

A. D. Pettee (General Cable Corporation, New York, N.Y.): The author, in Figure 15, indicates that the expanded 1.77-inch conductor has much higher loss than the bundle conductors. The expanded conductors which he tested, according to my source of information, were not conductors with as smooth an external surface as can be secured with the hollow-core (HH) construction as produced in this country.

Table I

Diameter of a Single Conductor, Inches	g
1.57	0.0705
1.77	0.0638
1.97	0.0585

Computation by the Carroll-Rockwell method[1] with an air density of 1.0, which, presumably, was substantially the condition in Cahen's tests, indicates that the 1.77-inch type-HH conductor would show losses of the same general order of magnitude as the bundle conductors, rather than the high losses for expanded conductors which Cahen has chosen to provide his comparison. It is important to know definitely whether Cahen's expanded conductors had a smooth, completely interlocked, external conductor layer or had an external layer of flat strips not thoroughly interlocked. If the latter is true, and there was an associated lack of smoothness, the high losses shown for the expanded conductor are not representative of the low losses which would be found with a smooth conductor such as the HH type.

I wish also to call attention to the drooping characteristics of the expanded cable loss curves in Figure 15 which contrast with the rising curves which are shown for the bundle conductors, and are also shown for the conductors studied in the Carroll-Rockwell paper. If the external surface of Cahen's expanded cable was not definitely smooth, it may explain the high losses in the lower part of his curves for expanded cable.

It is apparent that Cahen is correct in his statement that experimentation has not been going on long enough to be able to draw definite conclusions on the comparison between expanded and bundle conductors. In this connection, it is expected that the Tidd Station corona-loss tests now under way at Brilliant, Ohio, will furnish further important data on the relative losses of expanded and bundle conductors, and will supplement such data as Cahen has submitted for our review at this meeting.

REFERENCE

1. EMPIRICAL METHOD OF CALCULATING CORONA LOSS FROM HIGH-VOLTAGE TRANSMISSION LINES, J. S. Carroll, M. M. Rockwell. ELECTRICAL ENGINEERING (AIEE TRANSACTIONS), volume 56, 1937, pages 558–65.

François Cahen: In answer to the discussion by Temoshok, I agree with him that mean maximum, minimum, and equivalent gradient formulas are no longer valid when the spacing between bundle conductors becomes insufficient when compared to their diameters. As a result of tests carried out on short lengths in a test cage, the approximation still holds good for a spacing between conductor axes equal to three times their diameter; on the other hand, in actual practice, spacings to be taken into consideration are much greater. For instance, minimum losses were obtained with a spacing of about 8 inches, that is, nearly 8 times the diameter of the conductors, and for reasons of a mechanical character, a spacing of at least 16 inches should be adopted on industrial lines.

With regard to the bearing of single conductors, the calculation of the theoretical surface-gradient is easy to make. For the experimental line at Chevilly, the ratio

$$g = \frac{\textit{surface-gradient (kv per centimeter)}}{\textit{phase-to-neutral voltage (kv)}}$$

would represent, under conditions identical with those for which curves on Figure 14 were computed, the values in Table I.

Therefore a cable of 1.77 inches gives a theoretical gradient slightly lower than the minimum equivalent gradient of the bundle.

The fact that this cable has given, when under test, much higher losses than those of the bundle is assuredly due to the bad surface condition of the conductor, attributable to the disjunction of strands in the outer layer, but due also to the fact that the air disruptive gradient on the conductor surface decreases, as Peek has already shown, when the conductor radius increases. This results in a decrease of the critical voltage and an increase of losses independent of any disjunction.

In answer to the discussion by Pettee, I shall state that the bad surface condition of 1.77-inch diameter conductor is certainly responsible in a large proportion, for the very high losses shown on Figure 15. Since the report was written, many other tests have been carried out, both on the line and in a test cage, on cables 1.77, 1.89, and 1.97 inches in diameter. The tests on short lengths carried out in a test cage eliminated completely disjunction of outer strands and permitted a careful cleaning of the surface of the cables. These tests have shown that under the best surface conditions, losses of single conductors in dry weather were still, after undergoing a thorough weathering process from five to ten times higher than those of the bundle, and that during rain the losses of single conductors were about double those of the bundle.

It seems, therefore, almost certain that the high value of losses of expanded cables arises independently of the disjunction of outer strands from a systematic cause; namely, the fact previously pointed out, that the air disruptive gradient decreases when the conductor radius increases. Moreover, the decrease of the field, when getting away from the conductor, becomes smaller with increasing radius of the conductor, so that dust, asperities, and water drops have a tendency to produce brushes all the more easily with bigger conductors. This explains in particular, the weak slope in the curves of losses of expanded cables observed by Pettee.

Tests on single, large diameter conductors are being pursued in France with the aim of determining the best type of conductor to be utilized for the equipment for future lines which are to be built for direct use at a voltage of 400 kilovolts without any preliminary utilization under 220 kilovolts. I shall be glad, in this respect, to know what results will be obtained at the station at Tidd.

In answer to the discussion by Bellaschi, I shall state that the comparison between a vertical and horizontal layout of bundle

conductors involves, on the one hand, the problems relating to the closing up of conductors and, on the other hand, the question of the cost of the line.

The first point is dealt with in Tables I and IV of my paper which point out an advantage of the vertical layout in avoiding the use of spacers for a span of 1,640 feet when the spacing between conductors is equal at least to 16 inches. However, since this report was written, we have been carrying out tests meant to render evident the risk of one wire twisting itself around the other following a sudden discharge of rime deposit. These tests have shown it was necessary to place at least one spacer in each span, even when using a vertical layout for the conductors; this of course lessens the interest of this latter disposition for areas exposed to the effects of hoarfrost.

With regard to the second point, a vertical layout costs more than the horizontal one owing to the fact that it requires slightly higher towers.

Pumping for Power in the Colorado Rockies

FRANK M. WILSON
ASSOCIATE AIEE

IT is the purpose of the paper to discuss features of the Granby pumping plant, which together with the Granby Dam and dikes, the Shadow Mountain Dam and dikes, and the Alva B. Adams Tunnel, constitute the major man-made facilities for delivering surplus water from the western slope of the Rocky Mountains to the eastern slope for irrigation and power development. The topography of the region makes possible the unique feature of pumping for power production on this project by utilizing for hydroelectric power generation the diversion water with its tremendous drop of approximately 2,973 feet as it flows down the eastern slope after it has been raised in elevation a maximum of 186 feet by the Granby pumping plant. This plant will require for pumping operation approximately six per cent of the electric energy which will ultimately be generated by the diversion water as it passes through seven power plants on its course down the mountains.

General Description of Project

The Colorado–Big Thompson transmountain water diversion project for irrigation and power development is being constructed in the heart of the Colorado Rocky Mountains by the Bureau of Reclamation. The main features of this project lie within a vast vacation area, and the project has been planned to preserve the fishing and recreational facilities of the region as well as the scenic attractions of Grand Lake and the Rocky Mountain National Park. This project provides for the annual diversion eastward through the Alva B. Adams Tunnel under the Continental Divide of 310,000 acre-feet of surplus water from the headwaters of the Colorado River. This water will be obtained from a drainage area of approximately 782 square miles varying in elevation up to 14,000 feet above sea level and lying west of the Continental Divide. Diversion of this water, which is the lifeblood of the arid west, was made possible by the Colorado River seven-state compact allocating 7,500,000 acre-feet annually to the upper basin states and by approval of the diversion to the eastern slope by the Western Slope Protective Association and by the Northern Colorado Water Conservancy District. The latter organization created under the laws of the state of Colorado has contracted to repay a part of the cost of the project.

The Green Mountain Dam, located on the Blue River west of the Continental Divide, is a link in this vast project and was built to protect the western slope water users against a possible water shortage due to diversion of Colorado River water to the eastern slope. Part of the total capacity of 154,060 acre-feet of water stored in the reservoir back of this dam will be used for the generation of electric power and part will be held in reserve to make up for any deficiency which may develop in the water users' normal supply as a result of the diversion. The Green Mountain power plant has an installed capacity of 21,600 kw and has an average annual energy generation of approximately 60,000,000 kilowatt-hours.

Granby Dam and four dikes will impound the water for diversion and will be of the earth and rock-fill type construction. The dam will have its crest at elevation 8290.5 and will have a width of 40 feet, a length of about 885 feet and a height above streambed of approximately 232 feet. The four dikes will each have a 30-foot crest width and their total crest length will be approximately 6,300 feet. The reservoir formed by the dam and dikes will have a surface area of 7,256 acres and a maximum storage capacity of 546,350 acre-feet of which 467,000 acre-feet is to be active storage. The water level in this reservoir will vary from a maximum elevation of 8,280 feet to a minimum elevation of 8,186 feet.

The Granby pumping plant which is being built on the north side of the Granby Reservoir about eight miles north of Granby, Colo., will raise the water from this reservoir up into Shadow Mountain Reservoir which will be connected by a short channel to an existing natural body of water, called Grand Lake.

Shadow Mountain Reservoir which will be formed by the Shadow Mountain Dam and dikes will add 1,356 acres to the 507 acre-surface area of Grand Lake. The water level in the reservoir and lake will vary from a maximum elevation of 8,367 feet to a minimum elevation of 8,366 feet. Since these bodies of water will be limited to a maximum variation in water level of one foot, they will provide only enough storage to correlate the pumping plant discharge with the required inflow to the tunnel. The water level in the Shadow Mountain Reservoir will be regulated by two 18-foot by 20-foot radial-type spillway gates which can be operated by either local manual pushbutton control, by automatic float control, or by remote manual control from the Granby pumping plant. Shadow Mountain Dam and dikes are of the earth and rock-fill type construction. The dam and dikes have a crest elevation of 8,375 feet and a crest length of approximately 3,100 feet. The dam has a height above the streambed of about 50 feet. For periods varying from one to as much as three months during the year the natural inflow into Shadow Mountain Reservoir and Grand Lake will supply all

Paper 48-200, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 7, 1948; made available for printing July 16, 1948.

FRANK M. WILSON is with the Bureau of Reclamation, United States Department of the Interior, Denver, Colo.

Figure 1. Location map of Granby Reservoir, Granby pumping plant, including the discharge conduit and canal, Shadow Mountain Reservoir, and Grand Lake

of the water required for diversion, and no pumping will be required. When the natural inflow exceeds the required diversion through the tunnel, the surplus water will be spilled into the Colorado River and stored in the Granby Reservoir. The possibility of using the pumping units for electric power generation during this period by diverting the surplus flow down through the pumps into the Granby Reservoir was considered. This plan was not economically justifiable, however, and was not included in the final design.

The 13.07-mile long Alva B. Adams Tunnel will carry the water by gravity flow from Grand Lake under the Continental Divide and Rocky Mountain National Park to the eastern slope. This tunnel, which is circular in section, has an inside diameter of 9.75 feet and has a capacity of 550 cubic feet per second. The west portal at the inlet end will take water from Grand Lake at a depth varying from 7.5 to 8.5 feet below the water surface in order to eliminate ice obstructions and to discourage entry of fish. The inflow to the tunnel will be regulated by two 9-foot by 10-foot radial-type gates which can be operated by either local manual pushbutton control, by automatic float control, or by remote manual control from the Granby pumping plant.

A location map of the Granby Reservoir, the Granby pumping plant including the discharge conduit and canal, the Shadow Mountain Reservoir, and Grand Lake is shown in Figure 1.

After leaving the east portal of the Alva B. Adams Tunnel, the water will pass through a series of siphons, conduits, tunnels, reservoirs, and a total of seven power plants on its way for use for irrigation purposes. Only a part of the diversion water will go through the last power plant in the series for release into the Big Thompson River. The seven power plants will have a total installed capacity of 154,300 kw and an estimated annual energy generation of 730,000,000 kilowatt-hours. Two of these power plants are now under construction, the Marys Lake power plant with a capacity of 8,100 kw and the Estes power plant with a capacity of 45,000 kw.

The developed profile and diagram of the project is shown in Figure 2.

Granby Pumping Plant

Building Design and Layout

The pumping plant is being constructed in a one to one slope excavation in sandstone approximately 115 feet deep. The pumping plant building will consist of a rectangular reinforced-concrete structure extending from 50 feet above to 14.5 feet below the finished ground level and resting on an open reinforced-concrete shaft, having a rectangular central section and semicircular ends, which extends approximately 117.5 feet to the bottom of the base slab. The lower structure will have interior cross-walls and beams and massive exterior buttresses for resisting the high external hydrostatic and earth pressures to which it will be subjected. The area around the pumphouse structure will be backfilled to elevation 8287.0 which is considerably higher than the original ground surface.

A ground mat of number 3/0 bare-copper cable covering an area of 5,460 square feet will be buried in the backfill over the intake pipes and connections will be brought to terminal boxes located in the walls of the pump floor. Bare-copper cable connections from these terminal boxes will ground all conduits, electric equipment, and exposed metal parts in the pumping plant and in the switchyard.

Six main floors will be provided in the plant in addition to the galleries for the intake and discharge valves. Four of these main floors will be below ground level and can be reached by both the stairs and the elevator. The semicircular longitudinal extensions of the building will house the elevator, stairs, cable, and pipe shaft, ventilating ducts, the drainage sump, and many of the plant accessories.

The gallery at elevation 8162.50 will provide access to the butterfly valves in the intake pipes and the gallery at elevation 8170 will provide access to the discharge valves, to the pump suction tubes, and to the end of the building under which the sump is located.

The floor at elevation 8186.25 will provide access to the main pumps and on it will be mounted the discharge valve control mechanisms, two sump pumps, the miscellaneous power distribution board, the unit auxiliaries power boards, the unit hydraulic gauge and control boards and other miscellaneous auxiliaries. The pumping units can be operated from this floor.

The main pump motors, the motor excitation-control cubicles, and the distribution transformers with secondary resistors for grounding the motor neutrals will be located on the floor at elevation 8211.25.

The intermediate floor at elevation 8252.50, which will provide storage space was built primarily for bracing the outside walls at this elevation.

The cable spreading room, the air compressor room, the oil purifier room, and the oil storage room are all located on the elevation 8272.50 floor. The switchyard transformers will be set down on this floor from above through a hatch for untanking operations. The two unwatering pumps for the plant, each with a capacity of 4,500 gallons per minute, will be mounted on a platform at elevation 8278.0 and will be accessible from this floor. These pumps will be used should the plant become flooded, and they can be used, if necessary, to supplement or replace the sump pumps in normal plant operation.

The service bay for the plant is to be located in the southeast end of the building extending from the ground-floor at elevation 8287.5 to the roof. This section of the building will provide unloading space for the equipment and also space for the storage of parts during the assembly and disassembly of the pumping units and transformers. The machine shop equipment will also be located on the ground-floor in this section of the building. Provision will also be made in this part of the building for a future emergency gasoline engine driven generator set to take care of the essential plant auxiliaries should all outside sources of power fail. The control room containing the motor-control switchgear, the line-control board, the supervisory control board, the telephone equipment, and the intake valve control board is also to be located on the ground-floor. The remainder of this floor will be occupied by washrooms, toilets, and miscellaneous rooms.

The electrical laboratory, the battery room, the ventilating equipment room, and the station-service room containing the unit substation switchgear and the miscellaneous power, heating, lighting, and d-c board will be located above the control room on the floor at elevation 8302.50.

The pumping plant will be serviced by three cranes for handling the equipment. The main 50-ton crane for the plant will be located in the service bay and will be used to unload equipment in the plant, to untank the switchyard transformers and to handle parts for the pumps, motors, valves, and other equipment through hatches in the subterranean structure down to the motor floor. The 25-ton crane above the motor floor will be used in assembling and dismantling the motors and to handle valve and pump parts and other equipment below the motor floor. The crane above the pump floor will be used for assembling and dismantling the pumps.

The building will be heated by electric space heaters with an installed capacity of about 390 kw and the ventilating sys-

Figure 2. Developed profile of the Colorado—Big Thompson Project showing power drop of diversion water on the eastern slope

tem has been designed to circulate approximately 20,000 cubic feet per minute of air through the lower part of the structure to keep dampness to a minimum.

A longitudinal section through the pumping plant is shown on Figure 3.

The general plan and profile of the pumping plant is shown on Figure 4.

Hydraulic Features

Pumps

Three vertical-shaft, centrifugal, single-stage pumps, each with a capacity of 200 cubic feet per second at the maximum pumping head of 186 feet, will be installed in the pumping plant. The 94-foot variation in the inlet head in the Granby Reservoir together with the long suction pipes and the low barometric pressure at this altitude made it necessary that the pumps be installed below the minimum reservoir level to insure freedom from cavitation throughout the wide operating range of head and discharge. As a result the centerline of the pumps will be located at elevation 8,180 which is six feet below the minimum reservoir level, and 107.5 feet below the ground-floor of the plant.

Intake Structure and Pipes

Each pump will be supplied by an 87-inch inside diameter concrete pipe approximately 570 feet long running from the intake structure located in the Granby Reservoir. Each suction pipe will be provided with an 88-inch butterfly valve located within the pumping plant and operated from the control room which is above the high water level of the reservoir. This valve will be closed when unwatering the pump for inspection and repair.

The radial-type reinforced concrete intake structure will be 40.5 feet high and will have its floor 15.5 feet below minimum reservoir level. The structure will have six radial openings with steel trashracks for the entrance of water. Provision is made to shut off the entrance of each of the three intake pipes by vertical slide bulkhead gates. A bulkhead gate will be closed only when it is necessary to repair a butterfly valve in an inlet pipe.

Discharge Valves and Pipes

A water hammer analysis has shown that the pumping plant will operate satisfactorily without a surge tank connected to the discharge lines and that water column separation will not occur in the suction or discharge lines under normal or emergency operating conditions. A minimum pressure of 14 feet below atmospheric pressure will be reached momentarily on the discharge line under emergency conditions when power failure occurs simultaneously on all three pump motors. A maximum pressure of 210 feet on the discharge line will be obtained under emergency conditions after simultaneous power failure on all three pump motors.

Each pump will discharge water through a steel pipe provided with a 76-inch butterfly valve. The butterfly valves will each be operated by hydraulic servomotors which receive oil from a central oil pressure system. For both normal and emergency operation the valves will be controlled to close $67^1/_2$ degrees in 12 seconds and the remaining $22^1/_2$ degrees in 30 seconds. The opening cycle will be completed in 16 seconds.

The steel discharge pipes will enlarge to 87 inches inside diameter beyond the butterfly valves and will be encased in concrete to the point beyond the plant where the branch connections from the individual pumps merge into a single reinforced concrete conduit having an inside diameter of 11 feet. The 11-foot diameter conduit will be approximately 3,413 feet long and will discharge through a siphon and over an apron into the Granby Pump Canal which will carry the water to the Shadow Mountain Reservoir. The invert at the crest of the siphon is to be at elevation 8369.0. An air-vent in the top of the siphon, interlocked with the motor circuit breaker, will prevent backflow from the canal. A float-controlled vacuum pump will be used to remove the air pocket at the top of the siphon and to insure full and efficient operation of the siphon during pumping operations.

Granby Pump Canal

This canal will carry the water from the conduit discharge to the Shadow Mountain Reservoir and will be about 9,380 feet long with a constant grade of 0.000146 and a capacity of 1,100 cubic feet per second. Most of the canal is being excavated in cuts, the maximum being about 68 feet. The canal discharge structure has two 12-foot by 12-foot radial-type gates which have the concave surface toward the reservoir to prevent return flow into the canal and to permit drainage of the canal for maintenance and inspection.

Electrical Design

Power Supply and Switchyard

The pumping plant through its adjacent switchyard will be connected by a 69-kv transmission line approximately 42 miles long to the Green Mountain power plant and by a transmission circuit of either 115 or 69 kv to the Estes power plant where it will be tied in to the power system on the eastern slope. Since operation of the eastern slope power plants is so closely tied in with pumping operations, reliability of power supply is very important. For this reason the pumping plant has been designed for two methods of motor starting, namely: Full-voltage starting when connected to the normal power system, and reduced-voltage starting when the transmission circuit to the eastern slope is out of service and the plant is connected to the minimum system through the 69-kv transmission line to the Green Mountain power plant.

The switching diagram for the Granby pumping plant is shown by Figure 5.

If the 115-kv circuit from the Estes power plant is selected, it will be tied to the 69-kv line from Green Mountain by three single-phase 7,500-kva delta-delta connected transformers located in the Granby switchyard.

The three 69-kv 600-ampere 3-pole single-throw outdoor-type power circuit-breakers in the switchyard will each have an interrupting rating of 500,000 kva at rated voltage and frequency.

Each motor in the pumping plant will be supplied by a 3-phase 5,750-kva 66- to 6.9-kv delta-wye connected, oil-immersed, self-cooled, outdoor-type transformer located in the switchyard. The high-voltage windings will have $2^1/_2$ and 5 per cent full capacity taps both above and below 66 kv. Reduced voltage for motor starting on the minimum system will be obtained by taps in the Y-connected low-voltage windings of the transformers. Three taps will be provided in each low-voltage winding to give reduced voltages of 30, 40, and 50 per cent of normal voltage. The Y-connected windings will give balanced voltages and currents for motor starting for whichever tap is determined by test in the field to be most suitable for the operating conditions. A phase displacement will not be involved in the motor transition from reduced to full voltage when the transformer low-voltage windings are wye-connected.

Full-voltage starting of the first motor will cause voltage dips on the 69-kv bus at Granby varying from 10.1 to 20.6 per cent of normal system voltage depending on the connected system, the type of transmission circuit to the Estes power plant which is selected and the initial voltages at the Estes and Green Mountain power plants.

Starting the first motor on the 40 per cent voltage transformer tap when con-

Figure 3. Longitudinal section through the Granby pumping plant

nected to the minimum system will cause a voltage dip on the 69-kv bus at Granby of approximately 10 per cent.

Motors

The three vertical-shaft synchronous motors driving the main pumps will each be rated at 6,000-horsepower 3-phase 60-cycle 327-rpm 6,600-volt and 0.95-power factor leading. The motors will rotate in a clockwise direction and will be designed to withstand the stresses resulting from operation at a runaway speed of 440 rpm.

The system constants under which the main pump motors will be designed to operate are as follows:

For the condition of reduced-voltage starting and synchronizing on the minimum system:

$$Z_s = R_s + jX_s = 0.16 + j0.90$$
$$Z_g = R_g + jX_g = 0.16 + j1.27$$

For the condition of full-voltage starting and synchronizing on the normal system:

$$Z_s = R_s + jX_s = 0.026 + j0.63$$
$$Z_g = R_g + jX_g = 0.026 + j0.74$$

Where Z_s is the external impedance from the motor terminals to the point of equivalent minimum system regulated voltage and Z_g is the external impedance from the motor terminals to the point back of transient reactance of minimum system synchronous machine capacity with all quantities expressed as per unit on a 25,000-kva base.

Each motor will be designed to start on the minimum system with 36.8 per cent of normal voltage across its terminals and an initial inrush of 4,000 kva when the pump discharge valve is closed, the water level in the suction tube is below the pump impeller, and the thrust bearing friction is reduced by pressure introduction of an oil film between the bearing surfaces. Each motor will also be designed to start on full voltage on the normal system with an initial inrush of 29,400 kva when the valve in the discharge pipe is closed, the pump casing is full of water and an oil film has been established between the thrust bearing surfaces. Each motor will have a synchronous condenser capacity of 2,200 kva when operating at rated voltage, leading power factor, and no load, with the discharge valve closed and the water level in the suction tube below the pump impeller. The motors will have a pull-out torque at rated voltage, frequency and field current of not less than 200 per cent of full-load torque.

The motors will each have a spring-type thrust bearing and a guide bearing above the rotor and a guide bearing below the rotor. A thermostat relay bulb will be embedded in the metal of the thrust bearing and of each guide bearing to operate an alarm on excessive bearing temperatures. Two resistance temperature detectors will be embedded in the thrust bearing metal of each motor for indication at the motor-control switchgear of the bearing temperature. A motor-driven oil pump mounted within the motor air housing will provide oil pressure lift to the thrust bearing during the starting operation. The thrust bearing will transmit its load, composed of the weight of the rotating parts of the motor and pump, plus the unbalanced hydraulic thrust, through a bearing bracket to the stator frame.

The motor armature windings are to be insulated with class *B* insulation, and the coils will have corona shielding and will be treated to prevent permanent injury from temporary exposure to dampness. Electric heaters with a capacity of 15 kw in each machine will be used to prevent condensation in the windings when the motor is not operating. Embedded resistance temperature detectors will give indication of armature winding temperatures at the motor-control switchgear. The armature windings of each motor will be Y-connected with three main leads and three neutral leads brought out of the stator frame. These windings are to be protected by differential current relays. The main leads will be connected to surge-protective capacitors and lightning arresters mounted within the motor housing. The neutral leads will be grounded through a distribution transformer having a secondary short-circuiting resistor. The field winding of each motor will also be insulated with class *B* insulation, and the field poles will have amortisseur windings adequate for starting, accelerating, and synchronizing the motor under the required operating conditions.

Each motor will have an enclosed ventilating system with a water-cooled surface air-cooler at one end. All cool air from the surface cooler will enter the machine from the top, and fans on the rotor will provide the necessary circulation. The complete cooler will be handled by the overhead crane through an opening in the air housing coverplate. A removable coverplate on one side of the air housing will provide access to the cooler for cleaning and removing tubes. The motors are being designed so that the maximum temperature rise of both the armature and field windings will not exceed 60 degrees centigrade when delivering rated output continuously with rated voltage, power factor, and frequency and with cooling air entering the motor at not more than 40 degrees centigrade. The cooling water temperature will not exceed 25 degrees centigrade as it enters the cooler. The thermal capacity and cooling system of each motor will be adequate to permit two complete consecutive starts at either reduced or full-voltage with a third start 10 minutes after the second start.

A corrosion-resistant metal ringheader having a minimum bursting pressure of 6,000 pounds per square inch and provided with discharge nozzles will be installed above the rotor for the carbon-dioxide fire-protection system. A pressure-relief door will be provided to prevent distortion of the air housing due to internal pressures caused by the release of the carbon dioxide gas.

Compressed air operated brakes furnished with each motor will be capable of bringing the motor and pump rotating parts to a stop from one-half speed within five minutes after application, without field excitation on the motor. The brakes will also serve as hydraulic jacks to lift the motor and pump parts for removal or adjustment of the thrust bearing and for removal of the pump intermediate shaft from below. The lifting jacks will be operated by a hand-operated high-pressure oil pump. Removal of the pump intermediate shaft will permit dismantling the pump without disassembling the motor. Each motor will be equipped with a direct-connected, d-c, vertical-shaft, shunt-wound, main exciter. Automatic voltage regulation will be accomplished by means of a regulator using a separate motor-driven amplidyne generator. This is to be one of the first applications of this type of regulator to slowspeed hydroelectric machines.

Control and Operation

Normal operation will be from the main control room on the ground level floor, but the pumping units may be operated from either the switchgear in the control room or from the unit hydraulic gauge and control boards located on the pump floor.

The supervisory control board located in the control room will provide recording, indication, telemetering, and control of remote features related to pumping and storage operations as follows:

1. Continuous recording of water levels in the tunnel, in Shadow Mountain Reservoir, in Granby Reservoir, and in the channel carrying overflow from Granby Reservoir.

2. Indication and telemetering of gate positions at the west portal of the tunnel and at Shadow Mountain Spillway.

Figure 4. General plan and profile of the Granby pumping plant, including the intake structure, the suction pipes, and the discharge pipes

Figure 5. Switching diagram for the Granby pumping plant

3. Remote control of the gates at the west portal of the tunnel and at the Shadow Mountain Spillway to place them under either automatic float control or remote manual control.

The line-control board in the control room will provide the control, protection, and instrumentation for the switchyard equipment and the transmission lines.

The motor-control switchgear in the control room will provide the control, metering, instrumentation, and protection of the three main pump motors and the control and indication of auxiliaries including the discharge valves. This switchgear is to be of the metal-clad type with removable circuit breakers and will be of the 15-kv class due to the high altitude of the installation. The reduced-voltage and the full-voltage circuit breakers in the switchgear will both have a continuous current rating of 600 amperes and an interrupting rating of 150,000 kva at 15 kv.

Selection of the full-voltage or the reduced-voltage motor starting procedure will be determined by the operator based upon the connected power system and will be made by the manual operation of a selector switch on the motor-control switchgear. With the pump discharge valve in the closed position, the next step will be the starting of the pumping unit auxiliaries, including the voltage-regulator motor-generator set, from either of the two control stations. Both methods of motor starting will involve pressure introduction of an oil film between the motor thrust bearing surfaces to lower the necessary starting torque of the motor. The reduced-voltage starting method will require, in addition, that the water level in the suction tube be depressed by compressed air below the pump impeller. After these preliminary operations, the motor may be started by the manual operation of a control switch at either of the two operating stations. Interlocking in the motor control equipment will prevent the motor from starting unless the unit auxiliaries are functioning properly and the following conditions exist:

1. The thrust bearing oil pump produces oil pressure.
2. The pump guide bearing oil pump produces oil pressure.
3. The pump discharge valve is fully closed.
4. Water flows to the motor air-cooler and the thrust bearing cooler.
5. Cooling water flows to the pump stuffing box.
6. The pump casing is unwatered (for reduced-voltage starting only).
7. Water flows to the pump seal rings (for reduced-voltage starting only).

When the selector switch is in the position for reduced-voltage starting, operation of either motor-control switch will close the reduced-voltage circuit-breaker in the switchgear applying reduced voltage to the motor which will start and accelerate to maximum subsynchronous speed as an induction motor. The motor will be synchronized at reduced voltage by the automatic application of excitation to the motor field at the optimum conditions of speed and rotor pole angular displacement. The reduced-voltage circuit breaker will then be opened automatically, and the full-voltage circuit breaker will be closed automatically in an open circuit transition to apply full voltage to the motor. Manual operation of a control switch will then introduce water into the pump casing until rated pressure at zero discharge is attained. The pump discharge valve will then be opened by operation of a control switch and actual pumping will begin.

The full-voltage starting sequence will be similar except the motor will be thrown on full voltage for starting and synchronizing, and the pump casing will be full of water during the operation.

A motor will be automatically shut down by any one of the following conditions:

1. Incomplete starting sequence.
2. Loss of motor field excitation, or loss of synchronism.
3. Unit overspeed.
4. Excessive pump casing water pressure.
5. Motor thermal overload relay operation.
6. Motor overcurrent relay operation.
7. Motor undervoltage relay operation.
8. Motor differential current relay operation.
9. Motor ground fault relay operation.

Carbon dioxide for extinguishing fire will be automatically released into a motor air housing upon operation of the differential current or ground fault relays for the motor or by operation of the thermal links in the air passage ahead of the motor cooler. Carbon-dioxide manual release stations will be provided on the motor-control switchgear and at the motor floor.

Provision will be made in the control equipment that tripping a motor off the line for any cause, including normal shutdown, will also perform the following functions:

1. Close the pump discharge valve.
2. De-energize the motor field contro land

voltage-regulator equipment including the motor field circuit-breaker and the exciter field contactor.

3. Apply the compressed air operated brakes by means of a speed switch on the motor after the motor has decelerated to a low speed.

4. Close a contactor energizing the motor heaters.

For normal shutdown, the pump discharge valve will be closed before the motor is tripped off the line to minimize system disturbances.

The following conditions will not automatically shut down a pumping unit, but the annunciator system will call them to the operator's attention for investigation and appropriate action:

1. Excessive temperature of pump stuffing box.

2. Excessive temperature of pump guide bearing.

3. Excessive temperatures of motor thrust or guide bearings.

4. Excessive temperatures of motor-cooling air.

5. Operation of motor carbon dioxide fire protection system.

6. Loss of power or low oil-pressure in discharge valve control system.

7. Failure of water flow to pump seal rings (when operating with pump casing unwatered).

The controls have been arranged to allow reasonably simple operation of the plant and of the pumping units by a single operator. However, in order to avoid undue complication in the control system certain functions will be initiated manually which could have been included in a completely automatic sequence for starting and placing the units in operation.

It is planned to operate the pumping units on system off-peak power which means that the units required for pumping will be started at least once a day.

No Discussion

The Space Charge Due to Corona

OTTO J. M. SMITH
MEMBER AIEE

A NEW technique for measuring the field strength and deducing the ion density about a wire in corona is needed. The research described herein was aimed at developing one such new method. A better understanding of the physics of corona and ion recombination can follow the application of new experimental techniques to confirmatory investigations of a-c corona phenomena.

The use of increasingly higher voltages in electrical engineering has brought the problem of corona and its effect upon the design and operation of equipment and transmission lines into a position of singular importance in research. It is desirable for an operating engineer to know the power loss due to corona on a line under various conditions, and for the design engineer to be able to predict the characteristics of a proposed line. Each must rely heavily upon empirical relationships. The continually accumulating data from research will eventually result in a more complete theory and less need for reliance upon empirical tests.

In this work, the field strength about a wire with a-c corona was measured directly with a crystal galvanometer connected between two probe screens. The net space charge density was derived from the field strength curves in a single mathematical step, using Poisson's equation. The experimental curves show clearly the mechanism of the ion motion, and their form is easily derived artificially from some simple hypotheses.

The position and motion of the ions about a wire in corona is the physical manifestation of the mechanism of corona. If the ion densities and motions are known completely, one can determine mathematically the less concrete field strength and voltage distributions. Unfortunately, the ion densities cannot be measured directly. In previous studies of corona mechanism, attempts were made to obtain the ion densities from measurements of the potential at different positions in space. This was inherently a difficult method. The field strength was proportional to the derivative of the potential with respect to the radius. The ion density was equal to the difference between two large numbers, one a function of the second derivative of the potential, and the other a function of the first derivative. Multitudinous values of potential had to be determined for small radius increments in order to have meaningful second derivative figures. Even so, small percentage errors in potential could cause large percentage errors in ion density.

If the original data are direct measurements of field strength, then one need compute only a function of the difference between points on the original curve and the slope of this curve. The amount of laboratory work required is reduced by one order of magnitude.

The previous investigators in this field used oscillograms of voltage and corona current,[1] electrostatic voltmeters with probes,[2-6] and rotary generating electrostatic voltmeters.[6,7] The determinations of space charge potentials with a single probe or exploring wire may be in error due to the inherent limitations of probe measurements. These have been conveniently enumerated by Loeb.[8] The primary assumption in all probe measurements is that the presence of the probe does not alter either the potential distribution or the charge distribution in the region to be studied. Even without a space charge being present, a potential determination with a probe is unsatisfactory, for the indicating instrument must have a very low capacity and a very high resistance. The probe potential will be changed by the admittance of the instrument, and leakage conductance might give a time variation of the potential that would be most annoying. In the presence of space charge, a floating probe will attain a potential so that the fastest moving ions will be repelled, or so that the net current from bombarding positive and negative ions will be zero. Thus, even if the measuring instrument connected to the probe takes no current, the probe will alter the potential distribution if the ion velocities are appreciable. If the current requirements of the measuring instrument are large, the charge density in the vicinity of the probe may be lowered. In this case, the probe potential will be determined by the net flow of charge to the probe and the resistance of the measuring instrument. There is always doubt concerning the actual potential which the space would have were the probe not there.

The mechanism of corona loss is most closely associated with ion movements and densities. This is what one would like to measure experimentally, but can not. They can be partially computed from the field strength using Poisson's equation. This relationship is derived in the Appendix. It is possible to compute the field strength from the potential distribution, but to get useful ion information from measured potentials via two successive computations is beyond practicality. One would prefer, then, to obtain his experimental data in the form of field strength curves.

W. G. Hoover[6] used two probes to measure the field strength about a wire in corona. This method reduced the inherent errors found in single probe measurements. The two probes were close enough together that the errors in the floating potentials of the two due to

Manuscript submitted February 10, 1948; made available for printing July 1, 1948.

Otto J. M. Smith is with the University of California, Berkeley, Calif.

This research was supported by the H. J. Ryan High Voltage Laboratory at Stanford University. The author wishes to thank W. G. Hoover for his many helpful suggestions, and Joseph S. Carroll, director of the laboratory, for his untiring and competent supervision.

Figure 1. Complete assembly showing the operating bench nine feet above the floor

Note the oscillograph, motor, and arc light on the swinging bench, and the cam switch on the table

bombarding ions were approximately the same, and therefore did not enter into the measured voltage between the probes. However, the change in floating potential due to ion collection altered the potential distribution slightly, and this indirectly slightly affected the field strength. The energy for the a-c galvanometer connected between the probes was derived from rotating the probe assembly as an electrostatic generating voltmeter, and this reduced to a minimum the drain on the space charge.

The author followed the practice of many of the previous investigators in using the familiar physical arrangement of a wire on the axis of a cylinder to confine the electrical field. This has many advantages over other configurations. The field is radial and symmetrical, and lends itself readily to mathematical treatment. The space inside of the cylinder is comparatively free from external fields and influences, and the dimensions can be chosen to simulate most desired conditions. It has the further practical advantage that very little equipment needs to be insulated for a high potential to ground. Figure 1 shows the test equipment.

The field strength was measured as the difference in potential between two probes. As mentioned before, the errors were due only to second order effects. The field strength error due to the accumulation of charges by the probes was zero near the half voltage radius, and approached the same percentage as the potential error near either the inner wire or the outer cylinder. The error was proportional to the ion density, and was always in the direction of indicating larger ion densities than actually existed. The results were not, therefore, in disagreement with fundamentals but only exaggerated the phenomena we wished to examine in the near vicinity of the inner wire or the outer cylinder. The field strength which was measured was the resultant value due to all of the contributing parts of the electric system, and included that due to charges in space, the potential between the wire and the cylinder, and charges on the wire and cylinder. It is this value which is needed for Poisson's equation.

Theory

Universal Field Strength Curve

The field strength is inversely proportional to the radial distance from the central wire. This is a hyperbolic distribution, and would plot as a straight line with a slope of Er equals $V/(\ln r_2/r_1)$ on a linear graph with co-ordinates of E and $1/r$. This is equation 20, Appendix I. There would be a family of straight lines, one for each voltage, each going through the origin. A vertical voltage scale for these lines could be constructed with the same values as the field strength scale, on the abscissa $1/r = \ln r_2/r_1$. Since V/E equals $r \ln r_2/r_1$, a universal curve for a given physical arrangement can be plotted as a single straight line on coordinates of V/E and r, with a slope of $\ln r_2/r_1$. This is shown in Figure 2.

If there is a charge present, it will cause the field strength curve to vary from its usual hyperbolic form. If plotted with the co-ordinates of Figure 2, those regions

Figure 2. Universal field strength curve for no space charge

The ordinate is the ratio of applied voltage to field strength in units of volts per volt per centimeter. The abscissa is the radius in centimeters. The slope is drawn for a center wire r_1 of 0.1295 centimeter and an outer r_2 of 91.5 centimeters

Figure 3. Graphical construction of total charge curve

The abscissa is the radial distance in centimeters, and the ordinate is the field strength and the net total charge in consistent units

with no charge would be represented by straight line sections, which if extrapolated, would go through the origin. Other connecting curve sections would indicate the presence of ions. The charge density is given by equation 17 in the Appendix

$$4\pi\rho = \frac{dE}{dr} + \frac{E}{r} \tag{17}$$

The density can be calculated from a field strength versus radial distance curve. dE/dr is the slope of this curve, which is negative. E/r is the slope of the line from the origin to the point on the curve under consideration; it is positive, and almost equal to $-dE/dr$. The numerical difference between these slopes in statvolts per centimeter divided by 4π is the charge density ρ in electrostatic units per cubic centimeter.

Total Charge

The amount of charge present may be shown quantitatively by using a special function of the charge density. This is the total net charge contained in a cylindrical shell, one centimeter long, one centimeter thick, and of a parametric radius r. This total net charge is designated by Q. It is a convenient notation, for Q does not vary as a cloud of ions moves radially, but can only change by diffusion, recombination, or the introduction of new ions.

$$Q = 2\pi\rho r = {}^1/_2(E + r\,dE/dr) \tag{22}$$

The area under a curve of Q versus r is the total net charge contained in the entire electric field per centimeter axial length of the cylinder. The area under the curve of Q between two co-ordinates r' and r''

is the total net charge per unit axial length in the cylindrical shell of internal radius r' and external radius r."

The total charge can be determined graphically from the curve of field strength versus distance. The construction is shown in Figure 3. The line AB is drawn tangent to the field-strength curve at the point A, which corresponds to the parametric radius R. This line has a slope of dE/dr. It intersects the ordinate line for the radius $2R$ at the point B. The vertical distance between A and B is equal to the term $r\,dE/dr$ in equation 22. The vertical distance from R to A is equal to E in electrostatic units. Since the slope is negative, $(E+rdE/dr)$ is equal to R to A to B, or the distance from point $2R$ to B. Since Q is one half of this value, a line is drawn from the origin to the point B, intersecting the ordinate RA at the point C. RC is the total net charge, Q, expressed in electrostatic units if the field strength E is measured in electrostatic units.

Experimental Procedure

Equipment

The large cylinder used was 12-feet long, 6-feet in diameter, vertical axis, bottom 3 feet above the ground, and made of 1/2-inch mesh galvanized iron wire screen. See Figures 1 and 4. The central wire was number 10 copper, 0.102-inch in diameter, which was connected to a 60-cycle variable voltage supply of 150,000 volts, 75 kva. The dimensions of the wire and cylinder gave a critical corona voltage of 48,500 volts peak or 34,300 volts effective between the wire and the cylinder.

Figure 4. Dimensions of the large cylinder and the probe screens

Figure 5. Circuit diagram of the power connections

The probe screens used to explore the field were two flat strips of 1/8-inch mesh galvanized iron-wire screen, placed inside of the large cylinder and parallel to the axis. The strips were 3/4-inch wide and $7^1/_2$-feet long, parallel to each other and spaced 0.5 centimeter apart. They were oriented with their flat sides perpendicular to a radius vector, so that they were occupying positions which were equipotential surfaces before their introduction. The screens were insulated electrically and mechanically from both the central wire and the cylinder, and yet movable, so that they could be placed at any desired radial distance. They were suspended vertically between the free ends of two horizontal booms, one above and one below the cylinder, which were carefully isolated and damped for 120-cycle and low-frequency building vibrations. Screens were chosen for probes in order to allow the free passage of ions. A two-foot guard ring was left at each end of the large cylinder to insure uniformity of the field.

The power connection diagram is given in Figure 5. The largest harmonic in the generated voltage was the third, and this had a magnitude of only 0.36 per cent. The peak voltage on the high-voltage secondary of the transformer, therefore, could be accurately computed from the measured effective voltage on the voltmeter coil.

The field strength measuring instrument was a commercially available crystal galvanometer mounted between the probe screens. The crystal was a bimorph, in which two flat rochelle salt crystals 2-inches long and 1/8-inch wide were cemented together with their crystallographic axes in opposite directions. One end was rigidly clamped, and the other carried a 1/8-inch square mirror. The whole was in a chamber of damping oil. Between the crystals was one electrode and each exposed face carried an electrode which was connected to the other terminal. A voltage applied between the two terminals caused a twisting motion which depended upon the relation of the longitudinal dimension of the plate to the crystalline axes. The deflection in radians was approximately proportional to the charge on the electrodes. The capacity of the crystal, however, varied with the temperature, so that the response of the crystal in radians per volt was a function of the temperature. The measurements were all made at constant temperature, so that no corrections were necessary for this work. Other crystal data were:

1. Maximum safe deflection, 0.05 radian
2. Minimum sensitivity, 0.0002 radian per volt (at maximum deflection).
3. Resonant frequency, 7,000 cycles per second.
4. Leakage resistance, over 100 megohms.
5. Capacity, 2,000 micromicrofarads.

Figure 6. Circuit diagram of the oscillograph

G is a 120-volt d-c generator. L1 is an arc light. M1 is a variable-speed, 6-volt, 1250-rpm, film-drum motor. L2 is the oscillograph internal light. M2 is a 120-volt 60-cycle synchronous motor driving the cam switches S5 and S6. The oscillograph shutter is spring actuated and solenoid tripped, turning in the direction of the arrow. E is a standard oscillograph element for the 60-cycle applied voltage timing wave

Figure 9. Crystal assembly rough position calibration

The experimental points and the theoretical curve are the same values as Figure 8, with both co-ordinates divided by V. The spreading of the points at 10 centimeters is due to insufficient accuracy of the crystal calibration

The light source for the crystal galvanometer was a razor blade slit upon which was focused the light from a d-c arc lamp. The slit was located outside of the cylindrical cage, and three feet from the galvanometer. The light from the arc slit was reflected from the crystal mirror back through a lens mounted in front of the mirror.

It then passed through a hole cut in the side of a standard type of magnetic oscillograph, through a shutter and collimating lens, onto a moving film. The dimensions of the optical system were: 20 inches from the arc light to the slit, 39 inches from the slit to the crystal galvanometer mirror, 46 inches from the mirror to the collimating lens, and one inch from the lens to the film.

The mirror was very small and light, and had some unavoidable imperfections. They were not important for short optical systems, but were very noticeable in the long system necessary for this work. Most of the mirror was therefore covered and shielded from the light, with only a portion having a single focal length being used.

A timing wave was obtained on the same film with the curve of field strength. This was produced by a magnetic oscillograph element, supplied from a 60-cycle voltage source of the same phase as the high-voltage applied to the wire in corona. The film drum speed was 240 rpm of a 16-inch circumference drum.

The oscillograph, film-drum motor, arc lamp, and light slit were all mounted on a swinging platform nine feet above the ground. The platform was built to rotate concentrically about the same axis as the swinging booms which supported the probe screens and the galvanometer. The platform was designed not to touch either the boom supports or the cage supports, consequently a special type of mounting was employed.

Figure 6 shows the oscillograph circuit

Figure 8. Crystal assembly voltage calibration

The experimental values of V_c are determined from film measurements of D and Figure 7. The theoretical curve was computed from capacity measurements and the applied high voltage. The deviation from a straight line indicates insufficient accuracy in the rough crystal calibration

Figure 10. Corrected crystal calibration

E_m is the peak field strength in volts per centimeter computed from the applied voltage and the crystal position. D is the measured peak oscillograph deflection. The curve above 15 millimeters was obtained from Figure 7

Figure 11. Corrected Position Calibration

The ordinate is volts per centimeter per kilovolt and the abscissa is reciprocal centimeters. E_m was determined from film measurements and Figure 10. The solid line is the same universal computed curve as Figure 2

diagram. The sequence of events was controlled by a synchronously-driven set of cam switches. Switches *S5* and *S6* were adjusted to close with a 0.25-second time interval between them, the time required for a single revolution of the film drum. An exposure was made by first setting the shutter in the closed, ready position. *S1* was closed and the arc light adjusted; *S2* was closed and the film speed adjusted. *S3* was closed and as soon as the cam was operating at full speed, *S4* was closed. *S5* opened the shutter and *S6* closed the shutter after one revolution of the film drum.

Figure 13. Time lag of the field strength zero after the applied voltage zero

Note that the peaks for successively higher voltages occur both at successively larger radii and at greater time lags

Calibrations

The crystal alone was calibrated by applying known voltages to the electrodes and measuring the deflections. These values are shown in Figure 7. The crystal assembly was calibrated by applying known high voltages to the wire-cylinder assembly, and measuring the deflections. These values are shown in Figure 8. The following notation is used:

V_c = peak volts on crystal
D = galvanometer deflection in millimeters at the film
r_1 = central wire radius
r_2 = large cylinder radius
r = radius of measurement, crystal position
V = potential difference, kilovolt effective
V_m = potential difference, kilovolt peak
E = field strength, volts per centimeter, effective
E_m = field strength, volts per centimeter, peak
C_c = capacity of crystal
C_s = capacity of probe screens
d = spacing of the probe screens, centimeters
$k = V_c/D$, crystal constant
$K = E_m/D$, field strength constant

The field strength and the crystal voltage can be computed from the applied voltage.

$$E_m = V_m/(r \ln r_2/r_1). \tag{23}$$

$$V_c = E_m dC_s/(C_c + C_s). \tag{24}$$

$$V_c = (V_m/r)(dC_s/(C_c + C_s) \ln r_2/r_1) \tag{25}$$

The crystal voltage is therefore a linear function of V_m/r. A curve computed theoretically from equation 25 is plotted in Figure 8 along with the experimentally measured calibration points.

The calibration points were obtained by measuring the galvanometer deflections for voltages from 7.5 to 30 kv, at radii from 5 to 60 centimeters. Figure 7 was used to get the crystal voltages from the deflections. These values were then plotted in Figure 8 versus the ratio of the effective kilovolt to the radius. Each group of points represents a single field strength at a series of radii. Deviations from a straight line indicate an error in the crystal calibration. A scattered group of points represents a capacity change with radius change, or inaccurate locating. If the straight line through the

Figure 14. Time lag of the field strength zero after the applied voltage zero

If these curves were continued, they would intersect the horizontal axis at 34.3 kilovolts. The spread between the 10 and 30 centimeter curves at 75 kilovolts indicates that the space charge occupies the region up to about 35 centimeters. The close grouping of the curves at 40 kilovolts shows that the main space charge does not extend beyond 20 centimeters

points differs in slope from the theoretical curve, it represents actual capacitances or spacings different from those used in the theoretical computation.

These same experimental data can be used for checking in another manner by plotting on co-ordinates of V_c/V versus $1/r$. These co-ordinates are the reciprocals of those used in the universal field strength curve. The reciprocals spread out the significant data a little more evenly, as is seen in Figure 9.

$$V_c/V_m = dC_s/r(C_c+C_s)\ \ln r_2/r_1 \qquad (26)$$

Each group of points represents a single radius and a span of field strengths. A scattered group means an inaccurate crystal calibration. A nonlinear curve means a calibration varying with the radius of measurement, and the lack of coincidence of the theoretical curve with the measured values is due to the same factors as before. These two figures show that a more accurate over-all crystal calibration is needed, and that there are no inconsistencies due to the position of the probes.

The most useful calibration constant for the future work is $K = E_m/D$, the ratio of the field strength to the measured deflection. This K was computed from the calibration data, using equation 23, and was plotted in Figure 10. The ordinate was exaggerated for added accuracy. The curve above 15 millimeters was obtained from Figure 7. A final check was made by using the new curve of K to replot in Figure 11 the data of Figure 9. The vertical co-ordinate is the ratio of the field strength to the voltage, instead of the ratio of the crystal voltage to the applied voltage, but the form and significance of the curve is the same. This is a corrected position calibration curve. It is a straight line, which proves that the probe position and presence does not affect the field strength and potential distributions measurably. Since the points all group together on the line, and there are no wide spreads, the percentage accuracy of the crystal and screen calibration is the same for all voltages, and is of the order of four per cent.

Measurements

Oscillograms were taken for voltages from 40 to 75 kv and at radial positions from 10 to 90 centimeters. Field strength versus distance curves, and total charge versus distance curves were plotted for 45, 90, 135, and 180 electrical degrees after the applied voltage zero for each potential. The forms of these curves were similar; the 75-kv data will be presented as representative.

A typical oscillogram is shown in Figure 12. A sharp change in slope of the field strength curve can be seen corresponding to the first burst of corona. The residual ions cause the field-strength zero to lag behind the applied voltage zero. The amount of this lag in electrical degrees is shown in Figures 13 and 14. As the voltage was increased, there was both a greater travel of the ions, and more of them, which caused the maximums of these lag curves to move up and to the right (to longer times and greater distances).

The field strength curves for 75 kv are given in Figure 15. To these were applied the technique shown in Figure 3, and the derived total charge curves are plotted in Figures 16 and 17. An analysis of these distributions shows a residual space charge, which near the central wire and outer cylinder has the same sign as the central wire had during the preceding half cycle. In the 50-centimeter region was a body of ions whose sign was opposite to that of the corona during the preceding half cycle.

At 45 degrees after the voltage zero, the total net charge near the wire was diminished by ions being pulled into the wire and discharged, and by new corona-formed ions moving outward. The ions near the outer cage were separated under the influence of the new electric field. The negative ions moved toward the wire, and the positive ions moved toward the cage, resulting in a small net positive charge at 90 centimeters. A pocket of slower moving old ions was left at 55 centimeters.

At 90 degrees after the voltage zero, the new ions have reversed the net charge out to 30 centimeters, and reduced it from 30 to 45 centimeters. The positive ions moving toward the outer cylinder have increased Q to .2 in the last 20 centimeters. The positive pocket at 55 centimeters was reduced by the motion into the region of the negatives from 75 centimeters. At 135 degrees after the voltage zero, the new ions have penetrated even further to 40 centimeters, and at 180 degrees there remained the same form of residual ion distribution as at the start of the half cycle, except with reversed signs.

Conclusion

A new experimental technique has thus been developed and tested. Its superiority lies in the ease of calibration and obtaining data. It is now practical and possible to obtain actual curves of ion densities and motions, and study their fundamental mechanisms. A method of calibration has been presented which will tell the investigator the magnitude and kind of error which the apparatus will introduce into the field. A further test of this method can be made by the application of accepted ion mobility values in the simplified quasistatic field equations,

Figure 15. Field strength versus distance for 75 kilovolts effective, 60 cycles

Figure 16. Total net charge versus distance for the first quarter cycle of an applied 60-cycle 75-kv potential

Figure 17. Total net charge versus distance for the second quarter cycle of an applied 60-cycle 75-kv potential

Figure 18. Artificial derivation of total net charge curves

The dotted line is the negative space charge; the light solid line is the positive space charge; the heavy solid line is the net space charge. The arrows show the directions the ions have been moving

which will yield gross results consistent with measured actuality.

The mechanism of the ion motions is similar to that represented in Figure 18. At zero time, a body of ions is assumed to be left over from the previous negative corona, and elsewhere there is a uniform distribution of positive and negative ions. During the positive half cycle, the negative ions would move toward the wire. A few low-mobility ions would be left near the outer limits of the corona-ion penetration. A large number of positive ions would be introduced due to the new corona, and these would have higher mobilities and move farther than the old negative ions coming in at large radii. At the end of the first 180 degrees, three distinct regions can be recognized. During the next half cycle, the positive ions would be pulled back, and a space charge due to negative corona fed out. Not all of the new positive ions would be collected, because some, due to aggregation, would have had their mobilities decreased. The residual net charge curve shown for 360 degrees in Figure 18 would be that expected if the physical phenomena matched this simplest of explanations. No consideration has been given to diffusion or recombination, though the magnitude of the latter determines the final values of ion densities in the middle region. Even so, this artifice results in a zero-degree curve remarkably similar to that determined experimentally. The net charge bumps in the middle region are due to pockets of ions of both signs moving back and forth through each other. The form of the distribution in this region is altered by changing either the large cylinder diameter or the applied voltage. Rough calculations of ion mobilities, by following characteristic net charge bumps in this region, yielded from three to four centimeters per second per volt per centimeter, which is not inconsistent with the precise values of other investigations.

More voluminous data would have warranted a more careful study of the derived space charge curves than has been given here. However, the main features of the observed ion motions can be explained in the preceding simple manner, and the theorem of the minimum hypothesis indicates that no further enlightenment can be obtained by the theoretical consideration of more complicated phenomena.

This work will not change methods of measuring or predicting corona loss, but the laboratory worker will be encouraged to realize that the ion densities and motions actually exist qualitatively as he has previously visualized them. Quantitatively, they can now be measured.

Appendix

Critical Corona Voltage

If a voltage is applied between a wire and a concentric cylinder, and raised beyond a certain critical value, a power loss occurs, which is accompanied by visible and audible phenomena at the surface of the wire. This phenomenon is corona, and the lowest value of voltage at which the visible glow can be seen in the dark is called the critical visual corona voltage. At this voltage, the gradient or field strength at the surface of the wire is

$$G = 31d + 9.55(d/r_1)^{1/2} \quad (1)$$

G is the field strength at the surface of the wire, necessary for corona, expressed in kilovolts per centimeter; r_1 is the radius of the wire, and d is the relative air density. The foregoing formula is equation 25a on page 64 of Peek's Dielectric Phenomena in High Voltage Engineering.[1] It was derived by considering that the breakdown gradient of air of 31 kilovolts per centimeter existed a short ionizing distance of $0.308\,(r_1)^{1/2}$ away from the wire surface.

The potential difference necessary to produce the critical field strength for a central wire in a cylinder of radius r_2 is

$$V = mGdr_1 \ln r_2/r_1 \quad (2)$$

The factor m was introduced to account for variations from the theory due to the surface conditions of the central conductor. If the potential is raised above this value, the corona increases, and generates ions around the wire. This large concentration of ions near the wire alters the field strength and potential distributions markedly.

Poisson's Equation

The problem of an electric field with distributed charge has been nicely treated mathematically. Maxwell's field equations are

$$\text{Curl } \boldsymbol{E} = -d\boldsymbol{B}/cdt \quad (3)$$

$$\text{Curl } \boldsymbol{H} = d\boldsymbol{D}/cdt + 4\pi j \quad (4)$$

$$\text{Div } \boldsymbol{D} = 4\pi\rho \quad (5)$$

$$\text{Div } \boldsymbol{B} = 0 \quad (6)$$

There are also the supplementary equations

$$\text{Div } j + \partial\rho/\partial t = 0 \quad (7)$$

$$\boldsymbol{D} = k\boldsymbol{E} \quad (8)$$

$$\boldsymbol{B} = \mu\boldsymbol{H} \quad (9)$$

$\boldsymbol{E}$ is the electric field strength in electrostatic units; $\boldsymbol{D}$ is the electric displacement vector, also in electrostatic units; $\boldsymbol{H}$ is the magnetic field strength in electromagnetic units; $\boldsymbol{B}$ is the magnetic flux density in electromagnetic units; j is the current den-

sity in electromagnetic units; k is the dielectric constant in electrostatic units; mu is the magnetic permeability in electromagnetic units; and c is the ratio of the units (radiation velocity).

In quasi-electrostatics, the magnitude of the rate of change of the electric displacement is very small compared to cj, so that in equation 4, dD/dt can be considered zero. A further assumption can be made that the rate of change of the magnetic field due to the flow of ion current is negligible, so that dB/dt can be considered zero. The first of Maxwell's equations becomes

$$\text{Curl } E = 0 \tag{10}$$

This condition is that of an irrotational vector field, for which case a scalar potential function V may be set up such that

$$E = -\text{grad } V \tag{11}$$

The potential V is simply the electrostatic potential of the field in space, and at the surface of the central wire, is the actual voltage applied between the wire and the cylinder.

Poisson's equation may now be derived.

$k = 1$, for air

$D = E$

$\text{Div } E = \text{div } D = 4\pi\rho$

$E = -\text{grad } V$

$$\text{Div grad } V = -4\pi\rho \tag{12}$$

$$\Delta^2 V = -4\pi\rho \tag{13}$$

$$\left(\frac{\partial}{\partial r} + \frac{1}{r}\right)\frac{\partial V}{\partial r} + \frac{1}{r^2}\frac{\partial^2 V}{\partial \phi^2} + \frac{\partial^2 V}{\partial z^2} = -4\pi\rho \tag{14}$$

Using the foregoing equation, an analysis of the electric potential for low-frequency fields could be made to yield the net charge density at any point. This is not practical, because the form of the equation makes the charge density sensitive to the slope of the voltage curve. Small errors in the voltage, or in the shape of the curve connecting the measured points, will cause very large errors in the charge density. The most direct attack to the cylindrical field is given by equations 5 and 8

$$\text{Div } E = 4\pi\rho. \tag{15}$$

$$\left(\frac{\partial}{\partial r} + \frac{1}{r}\right)E + \frac{1}{r}\frac{\partial E}{\partial \phi} + \frac{\partial E}{\partial z} = 4\pi\rho. \tag{16}$$

Since guard rings are used at the ends, the second and third terms are zero.

$$dE/dr + E/r = 4\pi\rho. \tag{17}$$

in the absence of chargers,

$$dE/dr = -E/r. \tag{18}$$

$$E = c'/r. \tag{19}$$

Evaluating the constant of integration,

$$c' = Er = V_1/(\ln r_2/r_1) \tag{20}$$

$$V_1/E = r \ln r_2/r_1. \tag{21}$$

Discussion

Bradley Cozzens (Department of Water and Power, Los Angeles, Calif.): The author in presenting the new and novel method of determining voltage gradient and from it total charge in the space surrounding a wiring in corona has added further proof and possibly more accurate information upon the existence and movement of space charges surrounding such conductors. While the experiments were limited to the classical arrangement of concentric cylinders, they serve definitely to establish further the complexity and multiplicity of items which affect the formation of corona upon electrical conductors. The distortion of the normal field, as indicated in Figure 15, resulting from the migration of charges, as indicated in Figures 16 and 17, serves largely to verify the difficulties encountered in attempting to predict corona losses by theoretical means. The many variables which exist on open-wire lines, coupled with the varying nature of space charge movements, wind velocities, and normal atmospheric ionization, give further emphasis to the necessity for determining corona loss on transmission line conductors on full scale line sections.

The brush patterns which occur serve further to complicate the problem of theoretical determination, observations having indicated that corona brushes may exist as much as two or three feet apart, with no visible evidence of corona between such positions. These complications, coupled with the variable movements as indicated in this paper, have made it relatively impossible to predict without actual test, the performance of bundled conductors for transmission line operation.

As stated in the last paragraph of conclusions, the information furnished in this paper probably will not change the methods of determining transmission line corona loss or corona loss measurement. They should, however, have definite application in connection with the design of electrical precipitators and other devices utilizing corona and charge migration. A further study of this nature in connection with multiple conductors might add materially to the basic knowledge and assist in establishing proper positioning of bundled conductors in transmission line practice. The author is to be complimented on his unique methods and a complete study of an interesting laboratory problem.

Joints and Clamps for Aluminum Conductors

GORDON B. TEBO
MEMBER AIEE

Synopsis: Experience with conductor joints and clamps in a large transmission system is outlined with particular reference to aluminum-aluminum and aluminum-copper connections. Three investigations are described in which outdoor exposure tests were made on live-line tap clamps, U-bolt clamp connections between ACSR (aluminum cable steel reinforced) and copper cable, and various types of sleeve joints in ACSR. During the exposure period of five to seven years, they were subjected to a load cycle, and periodically, measurements of electrical resistance were made. Following the exposure, specimens were examined for corrosion, and subjected to heat runs and short-circuit current tests. Live-line tap clamps of the screw type were found superior to spring type. Preferred material for clamp surfaces in contact with ACSR was aluminum. Coatings of zinc or tin on bronze clamps retarded corrosion of the ACSR strands. In U-bolt clamps serious corrosion of ACSR strands occurred where they contacted clamp parts of copper, even though the copper was coated with zinc or cadmium. Aluminum separators between copper cable and ACSR maintained the lowest resistance and caused least corrosion. The use of No-ox-id lessened corrosion especially where dissimilar metals were in contact. Hydraulically-compressed sleeve joints in ACSR were superior to those pressed with hand tools or twisted sleeve joints. The resistance of twisted sleeve joints was affected more than compression joints by variations in type of filler. The application of these and other observations to field practice is discussed. The result of improved jointing techniques is illustrated by an analysis of resistance values on some 250 compression joints in ACSR measured during construction of high-voltage lines. Fields for further research are indicated.

Introduction

DIFFICULT problems confront every electrical utility in maintaining connections in electric conductors and in adding thousands of new ones each year. On an industry-wide basis, the magnitude of these problems warrants extensive research. Electrical utilities must take the initiative in solving them because their workmen make most of the connections and their plant is the proving ground for new designs and methods.

While important contributions have been made to the understanding of electric contacts between metals,[1,2] aluminum has received scant attention. Aluminum as a conductor material now predominates in several countries, and finds increasing application in others, hence the special problems of aluminum-aluminum and aluminum-copper connections require attention.

Joints in transmission lines are expected to possess high electric conductivity and mechanical strength and to retain both qualities for the entire life of the conductor. This may involve exposure to extreme variations in temperature and tension, vibration stresses, short-circuit currents, and atmospheric corrosion for a period of 50 years or more.

Predictions of such long-term performance from results of accelerated life tests are not convincing. Salt spray or fume cupboard tests may represent exposures found at the seacoast or near chemical plants, but such conditions are not common. A better basis for evaluating joints and clamps is to be found in past experience, supplemented by long-term life tests under controlled, but not highly accelerated conditions.

Experience

That it is possible to make good and durable joints in aluminum as well as copper conductors has been proved by experience extending over a 40-year period. Unfortunately, even among types which have been generally satisfactory, occasional failures occur. Less satisfactory types produce more frequent failures. Failures usually occur at times of heavy electrical loading and cause serious interruptions.

Good mechanical characteristics of conductor joints and clamps can be assured by applying well understood principles of design, selection of materials, and good workmanship. The attainment of good electrical characteristics has proved more difficult and most failures are attributed to poor electrical conductivity.

In a transmission system employing both aluminum and copper conductors, almost all troubles in electric connections are associated with aluminum or aluminum-copper contacts.

Twisted Sleeve Joints in ACSR

Although considered inferior to compression joints, twisted sleeve joints are still used in locations where hydraulic presses are difficult to manipulate. Deterioration is indicated first by increase of resistance and heating. This is followed in extreme cases by the appearance of holes in the sleeve, produced by internal arcing, and finally the conductor fails mechanically at or near one end of the sleeve. The typical external appearance of a defective twisted sleeve joint is shown in Figure 1.

Compression Sleeve Joints

Experience with compression sleeve joints has been generally satisfactory. Occasionally, however, an aluminum conductor burns off at or near a compression sleeve. Examination usually discloses improper cleaning of conductor or sleeve.

Paper 48-202, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 2, 1948; made available for printing July 2, 1948.

Gordon B. Tebo is with the Hydro-Electric Power Commission of Ontario, Toronto, Canada.

The author wishes to acknowledge the guidance of the Hydro-Electric Power Commission research committee on joints which sponsored these investigations.

Figure 1. Defective twisted sleeve joint in ACSR showing holes in sleeve due to internal arcing

The resultant high resistance causes heating, arcing, annealing, and finally rupture of the conductor.

The location of this rupture is usually just at entry to the sleeve, but is sometimes a foot or more away from the sleeve. Investigation in such cases has shown high interstrand resistance in the joint with consequent uneven current distribution. The few high conductivity, but overloaded strands, become red hot in the vicinity of the joint. Maximum temperature may occur some distance from the sleeve because its mass acts as a cooling medium. An arc produced by rupture of an overheated strand or by voltage difference between strands may induce progressive failure of adjacent strands. Such failures usually occur in periods of heavy load, not under fault conditions. A typical failure is shown in Figure 2.

For the other end of the sleeve joint shown in Figure 2, the resistances between individual strands and the sleeve were measured. With three volts applied all but four strands appeared open circuited. With 110 volts applied, the resistance values shown in Figure 3 were obtained. Of the five strands showing lowest resistance, one had fused off, and the other four showed signs of extreme heating and arcing to adjacent strands.

Threaded Connections

A compression sleeve joint, shown in Figure 4, employs a current-carrying threaded connection to join the two halves of the aluminum sleeve. This type has a very bad operating record. After 20 years in service on a 110-kv line, several hundred such joints in 312,000 circular-mil ACSR were tested, and more

Figure 2. Failure at compression joint in 820,000-circular-mil aluminum conductor

Figure 3. Resistance in milliohms between individual strands of 820,000-circular-mil aluminum conductor and sleeve measured at defective joint shown in Figure 2

Strands indicated by arrows showed signs of severe overheating

than 50 per cent had a resistance greater than ten times normal. In most cases the high resistance was in the threaded connections, not in the compression connections between sleeve and conductor. In some cases, almost all current was carried by the steel twisted sleeve. The trouble was attributed to inadequate cleaning and tightening of the threaded connection when installed.

The electrical conductivity of such joints was restored by welding across the threaded connection without lowering the conductor. However, the mechanical strength had been impaired by rusting of the steel sleeve and in one case, the joint parted during the welding operation. Fortunately the welder was supported by a line fastened to a second conductor. Most joints of this type were later replaced.

Clamped or Bolted Connections

Few actual failures have occurred at clamped or bolted connections but many have been averted by inspection and maintenance. Substitution of Everdur for steel U-bolts in clamps for large ACSR conductors proved beneficial. This was attributed to similarity of temperature-expansion characteristics of Everdur and aluminum. Where clamp connections between aluminum and copper conductors occur on important lines, they are inspected annually. When any burning of contact surfaces is found, it is on the aluminum side of the connection.

Compression Dead-end Bodies

The dead-ending of ACSR lines on copper disconnecting switches has been a

Figure 4. Threaded compression-type sleeve joint in 312,000-circular-mil ACSR

A—Welded to restore conductivity of threaded connection
B—Section of joint which failed in service

source of trouble. Recent practice has been to press bronze dead-end bodies directly on the ACSR and bolt the dead-end bodies to the copper switch. Coating the inside of the bronze sleeve with aluminum solder to minimize galvanic corrosion was, if anything, detrimental. Some failures, where the dead-end body was mounted with open end up, were thought to be due to water freezing in the sleeve and forcing the conductor outward.

Investigation of Live-Line Tap Clamps

Connection of pole-type transformers to primary conductors by means of live-line tap clamps is a growing practice. Anticipating some 100,000 installations, it was desired to evaluate two available designs

Figure 5. Live-line tap clamps used in five-year exposure test

A—Screw-type
B—Spring-type

Figure 6. Resistance of live-line tap clamps on number 4 ACSR during five-year exposure test

Numerals in brackets indicate number of specimens included in average plotted

of clamp, and to determine what clamp materials would be suitable for use on aluminum conductors. It was decided that only a long-time exposure test would satisfactorily answer these questions.

Procedure

Short spans of number 4 ACSR were erected in Toronto, Canada, near the shore of Lake Ontario. This was considered a normal urban exposure, combining high humidity and industrial smoke but free of salt spray or concentrated chemical fumes. On these spans were erected 37 clamps of the two types shown in Figure 5.

Clamp materials included aluminum,

Figure 7. Corrosion of ACSR strands at bronze live-line tap clamp due to five-year exposure test

Deep corrosion cracking is evident at edge of clamping area

Figure 8. Specimen U-bolt clamp connection between ACSR and copper subjected to five-year exposure test

bronze, and bronze coated with zinc or tin. The contact surfaces of clamp and conductor were cleaned with emery, and immediately assembled. The screw-type clamps were uniformly tightened to produce a load of about 1,500 pounds on the contact surfaces. The spring type was designed to exert a force of 40 pounds. An alternating current of 0.5 ampere was carried continuously by each clamp connection.

Summary—Live-line Tap Clamps

On the basis of resistance values measured annually, shown in Figure 6, and visual examination at the end of the five-

Figure 9. Resistance between ACSR and separators of various materials during five-year exposure test on U-bolt clamp connections between ACSR and copper cable

A—Satisfactory—minor pitting
B—Unsatisfactory—deep pitting
C—Serious—strands burned by arcing

year exposure, the following observations were made:

All spring-type clamps developed resistances exceeding 1,000 microhms which is considered unsatisfactory. Treatment with No-ox-id delayed but did not prevent increase of resistance.

Screw-type clamps of any material tested maintained resistance values less than 1,000 microhms. This is considered satisfactory since at a normal current of 10 amperes, the maximum loss would be 0.1 watt.

Uncoated bronze clamps caused serious corrosion of aluminum strands as illustrated in Figure 7.

Coating of tin or zinc on bronze clamps did not materially affect resistance values, but did lessen corrosion of the ACSR. However, the zinc (hot dip galvanizing) had corroded exposing bronze in the contact area.

The threads of the all-aluminum screw

Table I

Condition of ACSR Strands	Type of Separator in Contact with ACSR
Satisfactory	Aluminum Aluminum, No-ox-id Copper, No-ox-id Copper, galvanized, No-ox-id
Unsatisfactory	Copper Copper, galvanized Copper, cadmium plated
Serious	Copper, zinc plated Copper, cadmium plated, No-ox-id

clamps were undesirably tight after exposure. The threads of the bronze screw clamps were satisfactory.

Investigation of U-Bolt Clamps Connecting ACSR to Copper Cable

In a distribution system, connections between aluminum and copper occur in such forms as bolted connections, compression joints, and clamps. A simple form of specimen was sought, variations of which could be subjected to the same outdoor exposure as described for live-line clamps. It was thought that basic data obtained from such specimens would be applicable to other types and sizes.

Procedure

A single U-bolt clamp, joining number 2 ACSR and number 2 copper cable was chosen as a specimen connection and is shown in Figure 8. The clamping surfaces were prepared by cleaning with dry emery paper, followed in some cases by coating with No-ox-id. The 3/8 inch Everdur U-bolts having 16 threads per inch were uniformly tightened with a torque of 100 inch pounds. Mica inserts were used between each conductor and the outer clamp castings so that all current would pass through the separator. The separator materials tested were aluminum, copper, copper plated with zinc or cadmium, and copper hot dip galvanized. Forty-eight such specimens in 2 groups of 24 each were connected in series, placed in an outdoor span, and carried an alternating current of 150 amperes, five minutes on and eight minutes off, for a five-year period.

Resistance

During the exposure period, resistance between each conductor and the separator was measured at least annually. The resistances from ACSR to the various separators for one group are plotted in Figure 9. The resistances between the separators and the copper conductors were not plotted, but remained below 70 microhms with the exception of five of the 48 specimens. In each of these five cases the resistance on the aluminum side first exceeded 1,000 microhms which probably caused heating and oxidation of the copper side. It is interesting to compare the resistance of aluminum separator to copper cable with that of copper separator to aluminum cable. After exposure, the resistance values for six specimens between aluminum separator and copper cable were 44, 31, 49, 42, 33 and 35 averaging 38 microhms. The corresponding resistance values between copper separator and ACSR were 285, 170, 82, 175, 140 and 132 averaging 164 microhms. This result leads to the observation that when aluminum and copper are to be joined electrically, aluminum should be the massive member.

Damage to ACSR

Following the exposure test, one specimen from each group of three was cleaned by an appropriate American Society for Testing Materials procedure and inspected for corrosion. The only member seriously corroded in any specimen was the ACSR, hence the specimens were classified into three groups according to condition of the ACSR as shown in Table I and illustrated in Figure 10.

Temperature Rise

Six specimens which covered a range of resistance from 90 to 2,000 microhms were selected for heat run tests at 150 amperes. From this test it appeared that clamp resistance must not exceed 300 microhms if a limiting temperature rise of 50 degrees centigrade is to be maintained.

Short Circuit Current Test

After dismantling one specimen from each set of three for examination, the remaining specimens were subjected to short circuit current tests. All clamps carried 1,000 amperes for two seconds and then 2,000 amperes for two seconds without visible evidence of damage and without any major change in resistance value. Currents were then increased until most specimens showed burned-off strands in the number 2 ACSR. The results of these tests are summarized:

All specimens with resistance below 1,000 microhms withstood at least 2,000 amperes for two seconds.

All specimens with resistance below 100 microhms withstood currents of 4,000 amperes for two seconds.

The mica inserts used in assembling these specimens caused three or four of the six aluminum strands to carry the total current. In view of this restriction, and the rather long duration of the test current (two seconds), it appears that short circuit currents of normal duration and several thousand amperes could be carried by specimens with resistance up to 1,000 microhms.

Figure 13 (right). Resistance of type B compression sleeve joints in number 2 ACSR during seven-year exposure test

Figure 14 (left). Resistance of type C sleeve joints in number 2 ACSR compressed with hand tool and subjected to seven-year exposure test

Figure 15 (right). Resistance of type D twisted sleeve joints in number 2 ACSR during seven-year exposure test

Summary—U-bolt Clamps

When excessive resistance developed in U-bolt clamp connections between ACSR and copper, it appeared first between the separator and the aluminum conductor.

Of the separators tested between ACSR and copper cable, aluminum was best in maintaining low electrical resistance and was satisfactory from a corrosion standpoint.

Coatings of zinc or cadmium on copper separators were detrimental to the maintenance of low electrical resistance and did not prevent corrosion and burning of the aluminum strands.

Treatment with No-ox-id had no beneficial effect on resistance values. However, it reduced corrosion of the ACSR strands throughout the five-year period, and appeared capable of giving protection for many more years except where burned away in high resistance connections.

U-bolt clamps for connecting number 2 ACSR to number 2 copper cable which maintain resistances of less than 300 microhms are considered satisfactory with respect to energy losses, temperature rise, and short circuit currents.

Investigation of Sleeve Joints in Number 2 ACSR

Procedure

In order to compare the performance of various types of sleeve joints in ACSR and the various filler materials available, four 150-foot spans of number 2 ACSR were erected outdoors. In these were installed 87 sleeve-type joints, tension was adjusted to 150 pounds and current of 150 amperes, five minutes on and eight minutes off, was maintained through the joints.

No attempt was made to clean the inside of the sleeves. The conductor was cleaned by rubbing the outer surface with dry emery cloth. In order to maintain uniform current distribution, all six-conductor strands were welded together midway between sleeve joints. The four types of sleeve joint tested and a sample weld are shown in Figure 11. With these were used various types of filler; No-ox-id grade A special, supplied by Dearborn Chemical Company, zinc-chromate in linseed oil, red lead in linseed oil, Duralox which is a mixture of No-ox-id and dur-aluminum filings, and a special joint compound also available from Dearborn Chemical Company.

Resistance

Resistance readings were made periodically and the results of a seven-year exposure are shown on Figures 12, 13, 14, and 15. The resistance readings are reduced to ratio of joint resistance to that of an equal length of conductor. Joints are usually considered satisfactory for ratios of less than one.

The sudden decrease in resistance of the twisted sleeve joints shown in Figure 15 at the sixth year was due to the breaking of a pole supporting the spans. The readings for the seventh year were taken after the fallen spans had been re-erected.

Summary—Sleeve Joints in ACSR

All sleeve joints hydraulically compressed (types A and B) maintained satisfactory resistance values through the seven-year period.

Sleeve joints compressed with hand tools (type C) gave erratic results.

Of the five groups of twisted sleeve joints (type D) only one had a resistance ratio less than one at the end of six years.

Figure 16. Distribution of joint resistances measured during line construction. Consistently low resistance values are attributed to design of extruded tubing sleeve, adequate cleaning procedure and proper compression

Sleeves for both 477,000-circular-mil ASCR and 336,000-circular-mil ASCR are approximately 25 inches long. Resistances of equivalent lengths of each conductor are 77 and 110 microhms respectively

The effect of the filler material on resistance value is more pronounced in the case of twisted sleeve joints than with compression joints. The filler marked "special" gave the lowest and most consistent resistance values in both twisted and compression joints.

Applications

Before the value of accumulated experience and data can be realized, they must be applied to improve existing practices. Some changes suggested by these investigations are shown in the following.

Cleaning Procedure for ACSR

The most important single requirement for good joints in aluminum conductors is that both sleeve and conductor surfaces be free of dirt and oxide films at the time the connection is made. To ensure cleanliness, sleeves for compression or twisted joints are now cleaned by dipping in caustic soda (Gillets Lye Solution), rinsed in water and coated with No-ox-id. The ends are plugged with cotton batting to keep the bore clean during shipment. This preliminary cleaning is followed in the field by wire brushing immediately before assembly.

Aluminum conductors, if old or blackened, are cleaned in the field by dipping in caustic soda, rinsed, and then subjected to abrasive cleaning. For the abrasive cleaning of single layer cables, emery cloth and Duralox is applied without

unlaying the strands. In multilayer cables, the outer layer or layers are unlayed, the inner layer cleaned with emery cloth and Duralox and successive layers similarly cleaned after re-laying. The cleaning procedures briefly outlined here have been written as a detailed operating instruction for field use.

Use of Filler Material in Joints

No filler material has been found, even among those containing metal filings or abrasives, which is a substitute for proper cleaning. The filler does tend to seal the interior of the joint from the atmosphere. Present practice is to use Duralox as a filler for all compression or twisted sleeve joints in ACSR. As a result of recent investigations, consideration will be given to the "special" filler. The use of red lead, zinc chromate, and similar paint fillers has been discontinued.

Separators for Copper-Aluminum U-Bolt Type Clamps

Recent practice for U-bolt clamps connecting small copper to aluminum conductors has been to use a separator of cadmium-plated copper. During the five-year exposure test, this type developed high resistance and caused deep pitting of the ACSR. Consideration is now being given to the use of an aluminum separator.

Live-Line Tap Clamps

Spring-type clamps have been found unsatisfactory due to the small contact pressure, and their use has been discontinued. Bronze screw clamps now widely used on ACSR appear harmful to the conductor. Coatings of zinc or tin on bronze clamps retard corrosion but are not a lasting preventive. The preferred clamp for use on ACSR is aluminum but because the thread of all-aluminum clamps tends to seize, it may be preferable to face the contact surfaces of a bronze clamp with a substantial thickness of aluminum.

Dead-end Bodies for ACSR

Present indications are that for connecting ACSR to copper switches, dead end bodies should be aluminum thus making the aluminum-copper junction at the bolted connection.

Field Testing of Joints

The final evaluation of the techniques now in use for making joints will be available only after many years' service. Nevertheless, some means of predicting future performance can be found from past experience. It has been observed for instance that for a given type, joints with the lowest initial resistance are most likely to remain low in resistance.

An instrument was developed for determination of resistance of joints being erected in new lines. It consists of an ammeter-millivoltmeter combination arranged for separate current and potential connections to the conductor, and supplied by a 6-volt storage battery. The results for some 250 new joints in 336,000- and 477,000-circular-mil ACSR are shown in Figure 16. These were compression sleeve type using the new extruded tubing sleeves.

This analysis shows that the resistance of the poorest joint in 477,000-circular-mil ACSR is lower than that of the best joint in 336,000-circular-mil ACSR. Also the maximum resistance value for each size of joint is less than half that of an equal length of conductor. Such results as these, in addition guarding against defective workmanship, are some assurance that the joints will remain good joints for the life of the line.

Future Program

Much remains to be done to consolidate the present knowledge of electric connections into engineering practice and to meet new problems as they arise. Profitable fields for research would include:

An exposure test for a 10 to 20 year period on simple specimen connections between various combinations of conductor materials. Observations would include periodic determination of resistance and corrosion. Variables to be investigated would be material, cleaning technique, unit pressure, shape, and coating. This should provide quantitative data for design of connections and selection of materials.

An investigation of current distribution between strands of large aluminum conductors at joints or clamp connections.

A search for a cleaning fluid or paste to simplify the present cleaning procedures for aluminum.

A search for a simple soldering or welding technique to join aluminum conductors.

Development of improved compression tools combining the lightness of hand tools with high pressures of hydraulic tools

Discussion

Figure 1

Frank Noakes and Shang-Jen Tsou (The University of British Columbia, Vancouver, Canada): We are very much interested in Tebo's paper as it ties in with some of the investigational work now being conducted at the University of British Columbia on techniques of making joints in aluminum cable steel reinforced (ACSR) conductors.

In the conventional ACSR compression joint the path of the electric current in the outer strands passes through two mechanical contacts, while for the inner strands the number of contacts is considerably more. We recognize that the present techniques of making compression joints is considered by many to be satisfactory. However, it is obvious that a continuous metal joint would be superior. Recent advances in welding make the construction of such a joint possible. Figure 1 of the discussion indicates how each strand of a 397,500 circular mil conductor may be brought out between two aluminum sleeves in preparation for "Heliarc" welding. In the finished joint the weld bonds the inner and outer sleeves and the individual conductors. The ends of the joint are compressed to prevent ingress of moisture which may be injurious to the conventional steel compression sleeve which connects the steel cores together. It was found, following a suggestion in the author's paper, that the individual strand resistance as measured between the central part of the joint and strands was uniform and equal to that of an equivalent length of strand. This shows that each strand was satisfactorily connected at the weld.

Over-all resistance, heat and mechanical tests indicate that the joint should be satisfactory in the field.

A Universal Telemetering System

L. DALE HARRIS
ASSOCIATE AIEE

IT IS BELIEVED that there is a need of a general telemetering method that can be applied to any one of a wide variety of telemetering problems. There is a need for some basic circuit or device that could be adapted readily to the metering of flow in a remote gas main, temperature in the cylinder wall of a remote aircraft, the current in a remote alternator, or the remote indication of any one of numerous measurable quantities of engineering interest. If the engineer merely had to adapt a basic telemetering device through minor modifications, the design of a device or circuit for a new telemetering problem might be simplified considerably. In this paper is found the discussion of such a basic telemetering circuit.

The particular telemetering system under discussion employs frequency as a translation medium; that is, the quantity to be metered at a distance is translated to an equivalent frequency at the sending end for the purpose of transmission. A method is described herein for converting various measurable quantities to equivalent frequencies for transmission over pilot wires, carrier current or conventional radio links. At the receiving end of the system the frequency is converted back to direct current or voltage in proportion to the original quantity to be metered remotely. This translation for transmission is needed to avoid the effect of changing transmission characteristics on the indication at the receiving end of the system. These various functions are performed by vacuum tube circuits which operate so that the accuracy of the indicator at the receiving end is essentially independent of drifting tube characteristics. A minimum number of moving parts are employed. In the telemetering of many of the common quantities, no moving parts are in the system except the voltmeter or ammeter used as the indicator at the receiving end. For example, an a-c teleammeter employs only tube circuits using simple conventional components at both the sending end and receiving end plus a simple d-c milliammeter as an indicator at the receiving end.

The over-all accuracy of this telemetering system is good. A particular laboratory model of an a-c teleammeter had a maximum error of 0.5 per cent.

General Principle

For this system of telemetering to find application, either the quantity to be telemetered must be a direct voltage or there must be a way of converting the quantity to an equivalent direct voltage. Fortunately, many measurable quantities can be converted to their respective equivalent direct voltages. Some examples are alternating and direct current, alternating voltage, resistance, power, flow, position, temperature, and pressure.

In general the telemetering system will include a d-c televoltmeter, a complete telemetering system, as illustrated in Figure 1, plus a converter at the sending end for converting the quantity to be metered remotely to a direct voltage. The d-c televoltmeter is basic to all applications of this universal system. Each new application merely requires that the quantity to be metered remotely must be converted to its equivalent direct voltage, then the addition of the basic d-c televoltmeter yields a complete telemetering system.

Figure 1 is a block diagram of this basic telemetering system, a d-c televoltmeter. Both of the converters shown in Figure 1 are tube circuits. The transmission circuit carries a low-frequency signal that may be amplified, detected, become a part of a modulated high-frequency signal, or otherwise manipulated in any of the conventional communication operations. Within wide limits, the output of the frequency-to-direct voltage converter is practically independent of the magnitude of the received signal. For this reason there can be no important error introduced into the d-c indicator at the receiver end by virtue of the ordinary changes in the transmission circuit and its associate apparatus.

The transmitter unit of telemetering systems other than the d-c televoltmeter must include an additional function as was mentioned previously. As an example, Figure 2 illustrates an a-c teleammeter. The added device, alternating current to direct voltage converter, is simply a rectifier and filter circuit. Block diagrams of other telemetering systems, operating on the principles described here will differ from that of Figure 2 only in the first block. The two functions illustrated in Figure 1 are common to all of the telemetering systems described in this paper.

The Receiver

Previous discussion has indicated that the receiver in this system must convert the frequency of the transmitted signal into its equivalent direct voltage to operate an indicating instrument to show the magnitude of the quantity that is in the process of being telemetered. Two separate converter units, each of which separately performs the foregoing function, are used in this telemetering system. One is used as part of the transmitter, and another is the complete receiver of the system. The lower half of Figure 3 showing the three vacuum tubes and the associated capacitors and resistors is a schematic diagram of the converter that is used in the transmitter. Since the schematic for the receiver unit is identical to that of this part of the transmitter, a separate figure for the schematic of the receiver does not appear in this paper.

Paper 48-204, recommended by the AIEE joint subcommittee on telemetering and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted May 24, 1948; made available for printing July 7, 1948.

L. DALE HARRIS is with the University of Utah, Salt Lake City, Utah.

At both the receiver and the transmitter, these circuits act independently as commutating circuits each to produce a direct voltage across R_3 that is essentially proportional to the frequency of the input signal appearing at the common terminal of the capacitors marked C. At any particular instant, the vacuum tube commutating circuit at the transmitter is receiving the same a-c signal as is transmitted to the receiver unit of the system.

In the receiver unit the voltage across R_3 or the current in R_3 is a measure of the quantity that is metered remotely; in the transmitter unit the voltage across R_4 is subtracted from the d-c input for a purpose to be discussed later.

These three triodes with the associated circuit elements operate such that capacitor C_1 is charged through tube number 2 to a constant direct voltage, a voltage regulated by one of the VR tubes, during each positive half of the cycle of the a-c input wave that appears at the two capacitors marked C. During each negative half of the cycle of the input wave, C_1 is discharged through tube number 3 into C_2. Capacitor C_2 discharges at a comparatively steady rate through R_3 or the indicating instrument that might be substituted in the place of R_3. During the positive half of the input cycle, tube number 2 is conductive and tube number 3 is blocked, and during the negative half of the cycle the reverse is true. Tube number 1 is used to give a 180 degree phase angle shift in the alternating voltage supplied to the grid of tube number 3. The capacitance of C_2 is very much larger than that of C_1 so that voltage across C_2 may be kept very small compared to the maximum voltage across C_1. In this manner C_1 delivers an essentially fixed charge to C_2 during the process of each cycle of the input a-c wave. Therefore, the total charge delivered to C_2 during a given period of time is practically proportional to the frequency of the input a-c wave. The time constant of the R_3—C_2 circuit is made large in comparison to the period of the lowest frequency of the input signal such that the pulses of charge delivered to C_2 are filtered to give a rather constant direct current in R_3 that is proportional to the input frequency. The time constants of the circuits for charging and discharging C_1 are made very small compared to the period of the highest frequency that might appear in the input signal. In this manner, C_1 is allowed to charge completely and then discharge completely during each cycle of the input signal.

Figure 1. Basic features of the universal telemetering system—a d-c televoltmeter

The Transmitter

The transmitter (Figure 3) of the d-c televoltmeter includes an electronic oscillator of the conventional saw-tooth type having its frequency controlled accurately by a small direct voltage applied to the pentode of this oscillator through a d-c amplifier stage. The details of this oscillator are discussed later. The direct voltage that controls the frequency of the pentode E_o, is the difference between two voltages: the d-c input voltage, E_{in}, and the voltage across R_4, E_4, and it will be shown presently that these two voltages are nearly equal. For purposes of this particular discussion, it is sufficiently accurate to assume that the frequency, f, of the oscillator, the transmitted frequency, is proportional to E_o, and that the commutating circuit operates such that E_4 is proportional to frequency. These conditions are written in an equation for steady-state conditions:

$$E_o = E_{in} - E_4 \tag{1}$$

$$= K_o E_o \tag{2}$$

$$E_4 = K_c f \tag{3}$$

Eliminating f and E_o leads to

$$E_4 = \frac{K_o K_c}{K_o K_c + 1} E_{in} \tag{4}$$

It is also to be noted that:

$$K_o K_c = \frac{E_4}{E_o} \tag{5}$$

From equation 4 it is seen that by making $K_0 K_c \gg 1$, E_4 approaches E_{in} in magnitude; thus we say that E_4 is made to track E_{in}. Now if the commutating circuit in the receiver is identical to the commutating circuit in the transmitter, E_4 at the receiver will also track E_{in} at the transmitter, or an instrument indication at the receiver tracks the voltage E_{in} at the transmitter.

In order to reduce the tracking error between E_4 at the receiver and E_{in} at the transmitter, the coefficient $K_0 K_c$ is made larger by inserting a d-c amplifier ahead of the grid of the pentode oscillator. However, there must always be a slight difference between E_4 at the transmitter and E_{in}. Therefore, if both transmitter and receiver commutating circuits had identical conversion characteristics, there may be a significant error between transmitter d-c input voltage and E_4 at the receiver. To reduce this error below significant magnitudes, it is only necessary to make a slight compensating difference in the conversion characteristics of the two converters.

Figure 4 shows a schematic of the saw-tooth oscillator circuit used as the source of the transmitted a-c signal. The direct voltage, E_o that controls the frequency of the oscillator is applied to the grid of a pentode through a d-c amplifier. The control grid voltage of the pentode fixes the anode current of the pentode. This anode current charges capacitor C at a steady rate until the grid-to-cathode voltage of the gas triode allows this tube to conduct and discharge the capacitor in a relatively short time. After C has been discharged, the arc is extinguished in the gas triode and the cycle then repeats itself resulting in a saw-tooth like voltage wave appearing across C. The rate at which C charges up and therefore the period or frequency of this wave or signal are fixed by the magnitude of the anode current of the pentode. Since this current is approximately proportional to the control voltage, E_o, the frequency of the oscillator is controlled by E_o.

Performance of a Telemetering System

Depending on the desired speed of response, the maximum frequency transmitted by the telemetering set need only be from 10 to 100 cycles per second. This is a significant fact when many telemetering, control, and communication signals must be transmitted over one channel, since the frequency spectrum consumed by each telemetering signal is propor-

Figure 2. Basic features of an a-c teleammeter

Figure 3. Transmitter—content of left-hand block of Figure 1

tional to the maximum frequency of the telemetering signal. Audio signals of moderate frequency can be used as subcarriers of several of these low-frequency telemetering signals so that many audio carriers can be impressed on one radio frequency carrier.

Within wide limits, the performance of the converters is made to be independent of the wave shape of the transmitted signal. To realize this result, it was necessary only to make the time constant for charging and discharging C_1 very small compared to the period of the telemetering signal of highest frequency. Since wave shape is of little significance, one may filter harmonics from the generated saw-tooth wave, clip the top, or perform other wave shaping operations with no significant effect upon the accuracy of the system.

In order that the telemetering error becomes very small, the conversion characteristic of the frequency to direct voltage converter in the transmitter unit is made slightly different from the conversion characteristic of the receiver. Figure 5 shows the result of this compensating change. The need for such compensation might be eliminated by introducing additional amplification ahead of the grid of the pentode in the saw-tooth oscillator.

The vacuum tube circuits in this system are of such a design that a change in any tube characteristic of ordinary magnitude will have a negligible effect on the accuracy of the system. This situation is achieved through the following two conditions:

1. Time constants of capacitor charging and discharging circuits are made very short.

2. The amplifier supplying the control voltage to the pentode in the sweep oscillator and the sweep oscillator itself are elements in a closed feed-back circuit so that any change in the operating characteristics of any element of this closed circuit is most wholly corrected in the action of a closed feed-back circuit.

In contrast to the vacuum tubes, the voltage regulator tubes are in such a position in the system, that any change in tube drop may produce an appreciable error in the system. However, these tubes generally speaking, are relatively stable in respect to time and ambient temperature; and furthermore, some selected tubes from an ordinary stock have characteristics of excellent stability.

For most applications, it is desirable that the volt-ampere consumption or burden of metering devices be small. In this telemetering system, the burden is directly related to the impedance of the input circuit to the initial converter unit that delivers the necessary d-c input voltage to the transmitter. For many applications this initial converter unit is another vacuum tube circuit, making it possible for the burden to be very small.

The over-all conversion characteristics of this system are essentially linear so that the system is applicable to telemetering totalization processes.

Telemetering of Power

Although this telemetering method is directly applicable to the remote metering of many different quantities; special problems arise relative to the telemetering of power. As far as the writer knows, there is no extremely simple circuit or device available that will accurately convert power to an equivalent direct voltage. Laboratory work indicates that electronic wattmeter circuits will not yield accuracies within one per cent where the voltage and power factor may change over rather wide ranges. Other devices that incorporate the basic wattmeter or watthour meter movements might be used but at the loss of simplicity. Thermal converters have possibilities also.

Figure 4. Schematic diagram of the saw-tooth oscillator

Figure 5. Effect of compensating adjustments to bring the telemetering error within desired limits

Conclusion

This simple telemetering system is applicable wherever the quantity to be metered remotely can be converted to an equivalent alternating or direct voltage. There are no moving parts in the basic system except the indicating instrument at the receiving end. The principle of operation is simple, incorporating only elementary tube circuits. Drift in tube circuit characteristics are ineffective in producing error. Volt-ampere burdens drawn at the input terminals at the transmitter ordinarily would be very small. The system is applicable to telemetering problems where totalizing is desirable or necessary.

Each telemetering signal requires a narrow band width. The maximum signal frequency that must be transmitted need not be more than 20 to 100 cycles per second depending on what speed of response is required. By using 100 cycles per second as the maximum signal frequency, the speed of response becomes of the same order as the speed of response of the ordinary instrument movement.

Discussion

Perry A. Borden (The Bristol Company, Waterbury, Conn.): While this paper describes an ingenious and presumably novel method of obtaining a frequency proportional to unidirectional potential, it would seem that the author has overlooked at least one serious limitation to the universal use which he claims for it. This is found in the necessity for translating the measured magnitude into a suitable voltage before the measurement enters the telemetering system proper. If the potential were of the order of 0.1 volt or less, the limitation would not be so severe. Ammeter shunts, thermocouples, and thermal converters can be utilized to obtain these relatively low potentials and thereby reproduce with a good degree of precision the respective quantities under measurement. The only information which the author has given with respect to the order of magnitude called for in his d-c controlling potential is that which may be implied from the curve in Figure 5, where the compensation is shown through a range of 0–10 volts. Not only is it impracticable to obtain such potentials from the devices mentioned before; but if these voltages were available, they could in many instances be directly utilized for the purposes of telemetering without the need of interposing the a-c link which forms the basis of this paper. The obtaining of such voltages as representative of the small potentials mentioned would almost invariably require the use of some form of servomotor, which would add to the complexity of the system, and which, if used, would in itself frequently provide a complete solution to the telemetering problem.

Where the transmitted magnitude is inherently associated with considerable mechanical force, as in the case of liquid-level gauges or position indicators, it is of course possible to utilize an adjustable slide-wire, which, while providing a convenient source of available voltage, demands a regulated potential supply. There would seem no object in employing the system under consideration in these instances where the measured quantity is basically represented by the deflection of a moving shaft or spindle.

The author's statements with respect to low volt-ampere consumption are somewhat confusing. The actual telemetering system which he has described would presumably obtain its power supply from a commercial service, where the restrictions or power consumption are not severe. As to the burden impressed upon any measuring circuit associated with the transmitter, it is not seen that (with the possible exception of measurement of d-c potential) the volt-ampere consumption is any less than that required by the primary measuring elements of the more common systems of telemetering.

It is noted that the receiving instrument converts the frequency of the transmitted signal into an equivalent voltage to operate a d-c indicating instrument. If, as is very common practice, a graphic record of the telemetered quantity be required, it will be necessary to utilize either a powerful direct-marking millivoltmeter, or, better, a self-balancing recorder of the potentiometer type. Either of these instruments superimposed upon the unit which converts the frequency into its equivalent d-c potential, will offset any simplification which might characterize the basic system, and eliminate such advantage as might otherwise be claimed over those systems in which the signal as received directly actuates the exhibiting instrument either in an indicating or a recording form.

H. C. Thomas (General Electric Company, West Lynn, Mass.): The telemetering system described by Harris has many desirable characteristics, foremost of which are fast time of response with continuous presentation. The use of the frequency of an electric signal as the translating means is particularly advantageous when the telemetering is accomplished over a carrier-current channel. An analytical evaluation of the equipment indicates that it should be relatively free from maintenance difficulties.

At the present time, a very important use of telemetering equipment is in connection with the generation and distribution of electric power. In this application, power, both active and reactive, is the quantity most often telemetered. The fact that Harris' system is not easily adopted to the telemetering of electric power will seriously limit its use in this field. Likewise, its use over pilot-wire channels may be limited because of high attenuation due to line inductance and capacitance, which are important considerations where frequency is used as the translating means. Thus, the objective of providing a general telemetering method that can be applied universally, which is certainly a desirable objective, has not yet been met. The author states that the overall accuracy of this telemetering system is good, and cites a 0.5 per cent accuracy for a particular laboratory model. It is important to recognize that instrument accuracy is closely associated with the conditions under which the instrument is used, and that the accuracy attainable in a laboratory more often than not is unattainable in any practical application.

The need to compensate for conditions in the transmitter by adjustments in the receiver may prove to be a serious objection with regard to flexibility of application and simplicity of operation. Ideally, the transmitter and receiver of a telemetering system should be independent of each other with regard to adjustments and calibration.

The output wave shape of the transmitter may lead to serious interference problems because of the large percentage of harmonics which it contains. This is especially true when the telemetering is accomplished over the type of carrier-current channel which provides several telemeter channels for each carrier frequency, using audio tones and double modulation. Also, the number of telemeter channels which can be provided using a single carrier frequency is less than could be provided if the output signal contained no harmonics.

To summarize, it appears that this telemetering system is very well suited for the telemetering of d-c quantities over some types of carrier-current channels, in applications where a high degree of accuracy and stability is not required. Its fast, continuous response makes it adaptable to control initiation, and its simplicity should result in minimum maintenance requirements.

Electrification of an Ore Haulage System

R. J. CORFIELD
MEMBER AIEE

TO HAUL, feasibly and economically, 30,000,000 tons of ore annually a distance of 14 miles posed a specific problem to the Kennecott Copper Corporation at its Utah properties. This problem has been solved by building an electric industrial trackage line between the open-cut copper mine at Bingham, Utah, and the two concentrating mills, one at Magna and one at Arthur, Utah. The new trackage, known as the Copperton line, went into operation on May 1, 1948.

The general territory included in this electrification project is shown in Figure 1. The road traverses a rolling country through numerous cuts and fills, crossing over a main highway three times and several secondary highways at grade crossings. Figure 2 shows typical terrain.

Copperton yard, some seven miles below the mine, serves as an assembly yard for empty and loaded ore cars. The ore trains to the concentrators go down a maximum grade of 1.35 per cent to Arthur Junction from where they are sent to Fogarty yard serving the Magna concentrator, or to Arthur yard serving the Arthur concentrator, according to the needs obtaining at the time. A 2-mile lay of double track, Cyprus Siding, permits passing of loaded mill-bound trains and empty mine-bound trains. Power is fed to the trackage system at a point near the lower end of Cyprus Siding. Throughout the entire main line the curvature has been held to a maximum of three degrees because of the speed and length of trains handled. The trackage consists of 131-pound rails laid on hardwood ties. Ballast is crushed smelter slag which is readily available in this section of the country. Despite the proximity of this district to the Pacific northwest, there existed a shortage of fir for ties at the time of construction which dictated the use of hardwood despite its greater cost.

This electric railway is an entirely new project and completely replaces the original haulage system which lay to the west in a fairly rugged terrain. The old system had a ruling grade of 2.5 per cent and curves as sharp as ten degrees. Its motive power was coal-burning, Mallet-type locomotives weighing 350 tons and having a starting tractive effort of 117,000 pounds simple and 98,000 pounds when compounded. These locomotives normally handled a train of 46 cars at an average speed of ten miles per hour upgrade. The new system is designed to handle 75 car trains at a speed of 25 miles per hour.

The old and new locomotive characteristics are indicated in Figure 3.

The rolling stock used on the old system and transferred to the new system consisted of special-type gondola cars weighing 24 tons empty and 116 tons when loaded with ore and ready for the downhill trip to the concentrators.

In 1924 the concentrator yards at Magna and Arthur were electrified at 600 volts for "dumper" locomotives whose purpose was to break up the delivered ore trains into cuts of 14 or 16 cars and spot these cars in the dumpers where they were emptied, after which they were pushed out of the dumper buildings to run by gravity to the lower end of the empty yards. Under the 1948 electrification the concentrator yards were electrified at 3,000 volts and a single cab (1/2 of a complete locomotive) serves as a dumper locomotive, handling cuts of 20 cars. The 3,000-volt electrification necessitates the use of "reach" cars between the locomotive and the car dumper for two reasons. First, the locomotives are physically too large to enter the building, and secondly, in the interest of safety, it was decided to dead-end the 3,000-volt catenary system outside the dumper building. The old locomotives in dumper service were sent to the mine where they are now operating.

Copperton yard (Figure 4) is electrified at 750 volts to accept the mine locomotives. The 3,000-volt locomotives also operate at 750 volts within this yard. It may be well to point out at this time that empty trains leaving the concentrator yards start up-grade to the mine, hence require full power. This fact decided 3,000-volt power in the Arthur and Fogarty yards.

The present electrification is a continuation of a program started in 1923 to completely electrify the mine at Bingham, the world's largest open-cut copper mine, both as to loading and transportation. This program, which was completed in 1928, includes 42 electric shovels and 67 85-ton 750-volt electric locomotives. Approximately 150 track miles of overhead trolley construction is required to serve the mine alone, from which is transported a total of some 67,000,000 tons of ore and waste material annually to Copperton yard or to the waste dumps.

Power

Kennecott Copper Corporation generates its own power for its operations in Utah in a modern steam-electric station having an installed capacity of 100,000 kw. This power is generated at 13.8 kv which is transformed to 44 kv for distribution to the mine, railroad, and concentrators. The 44-kv power to the mine is transmitted over a 2-circuit steel tower line so routed as to go through the railway rectifier substation and there to supply power for the railroad.

Comparative economic studies made to determine voltage and current characteris-

Paper 48-205, recommended by the AIEE transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24-27, 1948. Manuscript submitted June 4, 1948; made available for printing July 14, 1948.

R. J. Corfield is with the Kennecott Copper Corporation, Utah Copper Division, Garfield, Utah.

The author wishes to acknowledge the assistance of J. S. Pearson, assistant electrical engineer, Kennecott Copper Corporation, Utah Copper Division, and to the electrical manufacturers who provided certain information in connection with the equipment which they furnished.

Figure 1. Map of trackage system and 44,000-volt transmission line serving the electric railway and mine

tics indicated that 3,000 volts of direct current was the optimum. Investigation of conversion apparatus dictated the selection of single anode rectifiers because of their adaptability to the high voltage selected, their efficiency, overload capacity, and low maintenance. The two rectifiers installed are believed to be the first of their capacity and voltage ever used for railway electrification in this country. They are each rated at 3,000 kw 3,200 volts, giving the station a nominal continuous rating of 6,000 kw. Figure 5 shows the general arrangement of the station. The control is fully automatic, metal-clad switchgear (Figure 6) with all instruments and adjusting devices facing inward to the control corridor so that an operator making a cursory inspection need not enter the rectifier and circuit-breaker rooms, which are ordinarily kept locked, as the rectifiers (Figure 7), rectifier auxiliaries, and high-speed circuit breakers (Figure 8) are all at a potential of 3,000 volts above ground. The automatic control used is conventional with the exception of the automatic transfer scheme for selecting either 44-kv line in case of a power failure on the line supplying the rectifiers.

The main line rectifier station is located at the economical load center, taking into account the spotting service of the 2-car dumper locomotives. This load center is not the geographical center, but lies somewhat closer to the concentrators than to the mine.

Two d-c feeders emanate from the rectifier station, each consisting of two 1,000,000 circular mils cables in transite conduit and terminated by means of potheads on a pole adjacent the station. These feeders are sectionalized at the pole, one feeder supplying the Bingham end, the other supplying the concentrator end, and are paralleled only when the locomotive passes under the trolley section break. Both rectifiers normally operate in parallel on the 3,000-volt bus supplying power to either, but not both, ends of the electrification. Such an arrangement is desirable in this particular case so that the load limiting and short-circuit detection equipment will function properly.

Power for the Copperton assembly yard at the mine, and the two feeder tracks to this yard, is supplied by two 750-kw 750-volt single anode-type rectifiers installed as a part of the mine haulage conversion equipment which consists of ten 1,000-kw 750-volt synchronous converters in addition to the two rectifiers. The part of the power system used for main line electrification is shown in Figure 9.

Catenary System

The catenary system used on this electrification was developed after a study of several proposed schedules of train operation, all of which took into account the operation of the two 125-ton car dumper locomotives. These were in spotting service on a $2^1/_2$-minute cycle, often with coincident peaks which were superimposed on the main line load. The maximum calculated peak was 2,600 amperes and it was desirable to limit the voltage drop to 15 per cent under this condition. Having determined the required conductivity, the problem became one of copper distribution, and, in the case at hand, a relatively light catenary was desirable as there are a number of deep cuts on this railroad and a derailment will require either shifting the overhead or removing it from over the center of the track. On the other hand, enough weight in the catenary system is required for stability.

The catenary finally selected consists of a 1/2-inch, 30 per cent conductivity, copperweld messenger; a number 4/0 stranded copper intermediate messenger and a 350,000-circular mils grooved trolley wire. The method of hanging the num-

Figure 4. Copperton yard from the mine end

ber 4/0 messenger and supporting the 350,000-circular mils trolley is shown in Figure 10. Main messenger tension was kept to a maximum of 6,590 pounds under an assumed loading of 1/4-inch radial ice on all wires and a 12-pound wind transverse to all wires.

In all yards, where 15 miles per hour is the speed limit, simple catenary (Figure 11) is used. That is, the number 4/0 intermediate messenger is omitted. Conductivity is ample, due to the large number of tracks which are all in parallel.

In order to provide the necessary additional conductivity, the catenary system is supplemented by two 1,000,000-circular-mils feeders which are connected alternately to the catenary every 1,000 feet. Feeders and catenary are sectionalized at the substation and all yards.

Detailed consideration was given to the question of steel versus wood for the supporting structures, and, while steel was preferred, it could not be economically justified on this electrification due, primarily, to the fact that past experience indicates a life of cedar poles in this territory at 20 years or more. The poles supporting this catenary system are fully treated fir, commonly known as "Blackjacks," rather than butt-treated western red cedar which were not obtainable. While fir poles, properly treated, have a good reputation, it is our first experience with them, and time alone will tell as to their life.

Both catenary and feeders are supported on standard 10-inch suspension disks, there being two in series. The decision to use double insulation was predicated on two facts. First, this railroad is out in the wide open spaces, subject to considerable target practice, and it was felt that the shooting of one disk would still permit operation until repairs were made. Secondly, this line traverses a rather severe lightning section, and continuity of service requires that flashovers be minimized as much as possible.

In addition to the catenary and feeder system, these poles support a signal control cable and a 2,300-volt signal power line (Figure 12).

Catenary construction was done in the conventional manner. The main messenger was strung to tension and clipped in advance of the auxiliary messenger and trolley. These conductors were strung together by a first stringing crew and temporarily clipped to the main messenger by means of hook wires. A second crew followed with a clipping car having a working platform 40 feet long. This crew did the final clipping, off-setting, pullovers, and dressing.

All rail joints are bonded with 7-inch, number 4/0 copper bonds, gas-welded to the rail head. Frogs are bonded in the conventional manner, and 2,000-ampere impedance bonds are installed at all signal locations permitting both rails to be used for the return of propulsion current.

Substations

The purpose and characteristic of equipment decided the design of the substation buildings (Figure 13). They are as fireproof as possible with no wood or other combustible material being used in their construction. All doors are steel and set in steel frames. No windows are used, structural glass block panels provide the necessary light. This results in a relatively dust-tight building which is a distinct advantage to the operation of automatic switchgear components such as relays and contactors. The building walls are concrete and brick, floors are concrete slabs on steel frames, the roof is gypsum plank and specification roofing. The interior walls and ceiling are lime plaster on steel lath.

Since the heat exchangers, which are located in the basement, dissipate considerable heat, vertical ventilating ducts built into the building entrance structures take cold air from above the building through intake fans which discharge directly in front of the heat exchangers. These intake fans are thermostatically controlled. Heated air is rejected through outlet ducts in the opposite side of the building entrance structures or through openings in the floor to mix with other heated air from equipment installed on the main floor. This heated air rises

Circuit breakers to extreme right and extreme left are on rectifier cathodes; other two are on lines to overhead system. Spiral stairway leads to basement

to the ceiling where grilled openings permit it to enter the space between the ceiling and the roof from where it is exhausted through a fan to the outside during warm weather and exhausts by chimney action during cold weather. The exhaust fans are manually controlled and run continuously during the summer months when outside temperatures reach a maximum of 100 degrees Fahrenheit. Roof drains are electrically heated to prevent damage to the roof from freezing water. All lighting in the station is fluorescent and lights are controlled by a timer. Most of the heat for the building is supplied by reject from the equipment, but 12 kw of supplementary heat is provided by electric convection heaters. The battery room is isolated to protect other equipment from corrosive or explosive fumes and has a separate ventilator discharging directly to the atmosphere. The degassing transformer (Figure 14) serves both rectifiers. High-voltage equipment in the basement is enclosed in wire screen.

The main rectifier transformers, station auxiliary transformer, and associated switchgear are of the outdoor type, and a conventional steel structure mounts the disconnecting switches, fuses, and lightning arresters. The entire outdoor yard area is mulched with an oiled gravel, graded for drainage and floodlighted from lights on the first towers adjacent the substation structure. The outdoor switchyard and the building are surrounded by a 6-foot fence on steel posts. All equipment mentioned in this paragraph is also shown in Figure 13.

Locomotives

The locomotives selected for this application are special in several respects. Of major importance was the fact that the duty cycle is rather severe due to the heavy trailing load up-grade and the speed required to maintain the tonnage between the mine and concentrators. It was also desirable to obtain as much electric braking as economically possible in order to reduce brake-shoe wear and promote safety. A thorough study was made of regenerative and dynamic braking. The final decision favored dynamic braking due primarily to the fact that rectifiers were to be used for a power source for this electrification. Inverted rectifiers, together with certain necessary locomotive auxiliaries, to permit regeneration, would have increased the first cost beyond the limit of economical justification.

These locomotives (Figure 15) feature all-welded construction. The trucks are exceptionally heavy, weighing approximately 40 tons each. The main deck plate is 2 inches thick and weighs approximately 20 tons. The cab structure and auxiliary equipment compartments are of welded-sheet steel and the cab is completely insulated. All compartment doors housing high-voltage control equipment are master keyed to prevent entrance of unauthorized personnel. All motors are equipped with antifriction bearings arranged for grease lubrication. Journal bearings are oil-lubricated by "felpax" wick lubricators with special attention to the journal thrust collar.

The articulated joint between the two trucks is of the ball-socket type, prelubricated and sealed against the entrance of foreign matter.

Two air compressors, each having a capacity of 75 cubic feet per minute, are installed in each locomotive cab.

Clasp brakes are used and air brake control is conventional except as modified to work in conjunction with the dynamic braking. This exception provides an electric interlock in the controller to prevent the application of independent air when the train is under dynamic braking but provides for train line brake operation from the locomotives.

Sanders are air operated and the piping so arranged that all wheels may be sanded in either direction.

The locomotive control is somewhat special due to the fact that the main-line locomotives use the mine-yard tracks thus requiring dual voltage control. Twelve 3,000/750-volt section breaks are installed at the lower end of Copperton yard to provide a 30-foot dead trolley section between the two systems. Main line locomotives will normally coast through the dead section with the master con-

Figure 9. Electric railway power system

Figure 10. Typical catenary spans used on main line

troller returned to its "off" position before the power collectors are de-energized. A selector switch in the controller must be manually positioned to agree with the system voltage, either 3,000 or 750 volts, before power may be applied to the traction motors. Should the engineer fail to make the correct selection of system voltage, the locomotive high-speed circuit breaker opens when the controller operating handle is moved to an "on" position.

The control equipment provides 2-speed motoring operation of the four traction motors from either a 3,000-volt trolley or 750-volt trolley. With 3,000-volt power the traction motors are connected four-in-series to secure 1/2 speed and then are connected two-in-series and two-groups-in-parallel to secure full speed. Free-running speed in the first (series) combination of motors is reached by fifteen evenly graduated resistance steps, these being the first to sixteenth notches of the master controller. Free-running speed in the second (series-parallel) combination of motors is reached by 11 evenly graduated resistance steps, these are the seventeenth to twenty-eighth notches of the controller.

With 750-volt power the traction motors are connected "series-parallel" to secure 1/4 speed and then all four motors are connected in parallel to secure 1/2 speed. Free-running speed in the series-parallel connection is reached by 13 evenly graduated resistance steps. These are attained on the first to sixteenth controller notches. (Notches 1, 2, and 3 maintain the same resistance value and are the equivalent of a single step.) Free-running speed in the parallel connection is reached by nine evenly graduated resistance steps. These are attained on the seventeenth to twenty-eighth controller notches. (Notches 17, 18 and 19 maintain the same resistance value and are the equivalent of a single step.)

The power circuits to trolley or ground are established by 48 electropneumatic contactors, divided into two banks of 24 each. They connect and commutate the resistors for motoring and braking operation. A series-parallel switch consisting of 17 cam-actuated contactors establishes the three motor combinations, "series," "series-parallel" and "parallel." Two similar electropneumatic switches, a reverser and a motor brake switch make the connections between the armature and fields of the motors.

A 5-pole switch serves to cut out one pair of motors, either numbers 1 and 2 or numbers 3 and 4, in case of a motor or circuit failure so that the locomotive may proceed under the power of two motors. With one pair of motors out of service, the remaining pair cannot be used for dynamic braking. Four overload relays, each one with a series coil in the circuit of a motor, are built into the cutout switch. These act to open the high-speed circuit breaker in the trolley circuit.

Relays that are energized directly from the trolley control the connections of the blower and compressor motors to suit the imposed voltage. They also control the high-speed circuit breaker to force the selection of the 3,000-volt or 750-volt circuits according to the line voltage.

Energized from the 3,000-volt system, two relays pick up and lock out a third relay and set up the control circuits for high-voltage operation. Energized from the 750-volt system, these two relays will not operate, and thus they permit the third relay to be energized through the action of its time-delay contact. After approximately $1^1/_4$ seconds this third relay will close and set up the control circuits for low-voltage operation.

Each traction motor and associated accelerating resistor is force ventilated by a separate blower. A 1,500-volt motor in each end cab drives four blowers, two for the traction motors and two for the resistors located at that end of the locomotive. Each of these motors also drives a 75-volt generator for charging the battery used for control and lights.

The two 1,500-volt blower motors are operated in series from the 3,000-volt line and in parallel from the 750-volt line. On 3,000 volts they start when magnetic contactors close under the control of the trolley relays. Two resistors limit the starting current on 3,000 volts and are shorted out by contactors under the control of relays when the motors reach approximately 1/2 speed.

On 750 volts they start when contactors close under the control of the third trolley relay. The starting resistors are not in circuit at this voltage. The blowers must run in order that the high-speed circuit breaker may be held closed and that the compressors may operate.

Figure 13. Main line substation

Entrance structure contains ventilating ducts to basement and attic exhaust fan duct

Two 1,500-volt compressor motors are operated in series from the 3,000-volt line and in parallel from the 750-volt line. The voltage across each of the series connected compressor motors is maintained approximately equal while the machines are above 1/2 speed by a connection between the mid-points of the blower and compressor motors. This provides a successful running condition but, to insure that both compressors will start, the voltage imposed on them is further equalized during the starting period by paralleling them with equalizing resistors.

These resistors are open circuited by contactors when counter electromotive force relays respond to the counter electromotive force of their respective machines. If one machine speeds up more than the other, the relay of the faster one, at approximately 1/2 speed, will take out the equalizing resistor connected across the slower motor causing an increase in its current, torque, and speed.

On 750 volts the starting resistors and equalizing resistors are not in circuit.

A cutout switch located in the operating cab control compartment provides a means for open circuiting the compressors in case of a fault in a compressor or its circuit. This permits multiple-unit operation of two locomotives, one with its compressors cut out in that class of service where the remaining two compressors can supply a sufficient amount of air.

Dynamic braking is arranged to develop maximum braking effort at approximately 24 miles per hour. A series of nine braking notches are provided, these being effective between 9 and 27 miles per hour without exceeding the motor rating or depending upon adhesion greater than 18 per cent.

The control equipment provides dynamic braking operation by disconnecting the motors from trolley power and using them as generators driven by the locomotive and dissipating the generated power in resistors. The motors are separated electrically into two groups and then the two motors of each group are paralleled with their fields transposed by means of a switch for purposes of stability and connected to a pair of accelerating resistors. Nine braking steps are obtained by commutating the paralleled resistance. Dynamic braking can be secured only when 3,000-volt power is available to produce full, forced ventilation of the resistors.

All regular control features, including dynamic braking and voltage selection are embodied in a single control stand. Cab interior is shown in Figure 16.

Communications

This railroad is equipped with the most modern types of signal and communication systems. A control board, installed at Copperton yard and operated by one operator on each shift, controls all train movements in and out of Copperton yard, all main line signals and switches, including two crossings of the main line by other railroads, and the switches and signals at the approaches of both concentrator yards. The control board is circuited by two types of systems. That part governing the Copperton yard is typical "NX" (eNtrance and eXit) interlocking which uses a unit wire control for each function. That portion controlling the main line, passing track and concentrator-yard approaches makes use of circuits whose relays operate by coded pulses. Where foreign roads cross the main line, electric locking and approach indication is provided and is under the control of the operator at Copperton. The passing track signals at Cyprus Siding are provided with a "Take Siding" indication since the schedule is so arranged that passing meets generally will be made within this 2-mile double track section.

All switches are operated at 24 volts and all signals at ten volts, the power being taken from batteries located at the operating device. Signals are colored light type. Dwarf signals (Figure 17) govern all the electrically-operated switches in the yards, while those controlling traffic on the main line are mounted on high masts.

Self-supporting aerial cable is used for control between the control tower and the signals and switch machines. This cable is multiconductor, there being 9, 15, 22, or 37 conductors, depending upon the location and number of functions to be controlled. Conductors are number 14 American wire gauge solid copper. This cable is supported on the catenary poles along the railroad.

All switches are electrically heated by tubular snow melters rated at 6 or 12 kw depending upon the length of the switch. These heaters are under the control of the operator at Copperton. Power for the heaters is furnished from the main line substation at 2,300 volts

Figure 14. Degassing transformer serves both rectifiers

An electric switch machine is shown in the foreground

which is transformed to 220 volts at the heater terminals. For charging signal batteries, 110-volt power is used from transformers on the same 2,300-volt line.

To supplement the signals, ultra-high frequency radio in the 152 to 162-megacycle band will be installed to provide telephone communication between the Copperton control tower operator, five fixed land stations and three mobile automobile sets. These automobile sets are for the use of the superintendent, signal supervisor and the maintenance of way supervisor. Railway mobile units are to be provided for all locomotives and cabooses to provide end to end communication, since a made-up train is approximately 1/2 mile in length, which practically eliminates hand or lantern signals even in fair weather. Connections are also provided for radio communications between the tower operator and train crews if necessary.

Conclusion

This electrified railway has not been in service long enough to obtain any definite operating data. However, results to date indicate that the calculated values as to power consumption, scheduled speeds, acceleration, dynamic braking, and general design of the entire project are more than adequate to meet the operating conditions proposed to the engineering department in the original premise.

No Discussion

The "Linascope"—An Echo-Ranging Type Fault Locator for High-Voltage Lines

J. R. LESLIE
ASSOCIATE AIEE

K. H. KIDD
ASSOCIATE AIEE

Synopsis: The "Linascope," an electronic fault locator is described which uses an echo-ranging method for determining the location and nature of transmission line faults. This device has been used on open-wire telephone circuits for the location of various fault conditions, including open and short circuits, and high-resistance joints. Tests have been performed on high-voltage transmission lines which were removed from service for the purpose. Artificial faults applied at distances as great as 300 miles were detected. Open and short circuit faults are readily observed. Transposition points give slight echoes. The equipment has been used for inspecting live lines. In this application a high-frequency pulse is used which is coupled to the line by means of a high-voltage coupling capacitor. It is intended to use photographic recording gear with this instrument for the continuous inspection of live lines, in order to locate transient faults such as occur with lightning flashover of live-line insulators.

THE inspection of circuits by pulse reflection methods is well known to communications engineers. In particular, this technique has been used in inspecting high-frequency coaxial telephone and television lines. A pulse-type fault locator was developed for the United States Army for locating faults on field quad cables.

More recently attention has been devoted to the application of this method for locating faults on power lines.

Paper 48-207, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24-27, 1948. Manuscript submitted December 11, 1947; made available for printing July 1, 1948.

J. R. Leslie and K. H. Kidd are both with the Hydro-Electric Power Commission of Ontario, Toronto, Canada.

When a voltage pulse of short duration is applied to the terminals of a transmission line, the wave travels along the line at a velocity which depends upon the line parameters. The wave velocity in cables ranges from 0.5 C to C where C is the speed of light (0.186 mile per microsecond). For all open-wire lines the wave velocity is constant for practical purposes and very nearly equal to the speed of light.

As the wave travels along the line it suffers some attenuation or loss in amplitude due mainly to the resistance of the conductors. There is also some distortion of the wave shape due to the nonuniform attenuation and delay of the frequency components of the wave. This distortion is very pronounced on ordinary telephone cables which have a nonuniform frequency response. On open-wire lines a voltage pulse travels with negligible distortion and only slight attenuation. The attenuation factor due to the resistance of the conductors is $\exp(-Rx/Z)$. Assuming a 4/0 copper conductor of surge impedance $Z=500$ ohms and a radio frequency resistance at one megacycle of $R=5.4$ ohms per mile, the foregoing formula indicates that a pulse must travel 130 miles to attenuate to one half its original value.

It should be noted that this paper deals with pulses of relatively small amplitude (1,000 volts or less). For lightning surges the attenuation is of course much higher, due to the presence of corona losses.

If at any point along the line there is an abrupt change in impedance then a portion of the incident wave is reflected back toward the source while the remainder of the wave continues in its original direction. Table I shows some of the more important impedance discontinuities which occur on transmission lines, together with formulae giving the magnitudes of the reflected and transmitted pulses.

It will be noted that at an open-circuit fault the echo is of the same magnitude and polarity as the incident wave. At a short circuit fault the echo is again of the same magnitude but is reversed in polarity. If the line is terminated in its characteristic impedance there is no reflection from the termination. In general, if the pulse is incident upon an impedance greater than that through which it is passing, an echo arises of the same polarity. If the pulse is incident upon an impedance lower than that through which it is passing, then an echo of reversed polarity occurs.

The fault locator described in this paper develops a short duration (approximately 25 microseconds) voltage pulse which is connected to the line under test. Echoes returning from any faults on the line as well as those from major impedance discontinuities are displayed on a suitable time base on a cathode ray tube. The pulse is generated repetitively in order to obtain a steady visual pattern on the cathode ray tube.

The time required for the return of any particular echo is then measured and hence the distance to the source of that echo is determined. The magnitude and polarity of the echo give information regarding the nature of the source of the echo. The choice of the cathode ray tube sweep and time measurement circuits are influenced by much the same factors that arise in their use on radar equipment. With the large number of precision circuits that are available, practically any desired degree of accuracy can be achieved in the measurement of the echo distances.

Portable Linascope Fault Locator

The considerations previously described led to the construction of a portable pulse-type fault locator. Since similar units

Table I. Typical Transmission Line Discontinuities with Formulae for Echo Magnitudes

Line With Shunt Resistance $Z=\sqrt{\frac{L}{C}}$ R	Incident ..... E_I Reflected $E_R = -\frac{Z}{2R+Z}E_I$ Transmitted $E_T = \frac{2R}{2R+Z}E_I$	When $R = 10{,}000\ \Omega$ $Z = 500\ \Omega$ $\frac{E_R}{E_I} = -2.5\ \%$
Line With Series Resistance $Z=\sqrt{\frac{L}{C}}$ R	Incident ..... E_I Reflected $E_R = \frac{R}{R+2Z}E_I$ Transmitted $E_T = \frac{2Z}{R+2Z}E_I$	When $R = 10\ \Omega$ $Z = 500\ \Omega$ $\frac{E_R}{E_I} = 2.0\ \%$
Change in Line Spacing $Z_1=\sqrt{L_1/C_1}$ $Z_2=\sqrt{\frac{L_2}{C_2}}$	Incident ..... E_I Reflected $E_R = \frac{Z_2-Z_1}{Z_1+Z_2}E_I$ Transmitted $E_T = \frac{2Z_2}{Z_1+Z_2}E_I$	Typical Transposition Gives $\frac{E_R}{E_I} = \pm 2.5\ \%$ Testing Phase to Phase
Terminated Line $Z=\sqrt{\frac{L}{C}}$ R	Incident ..... E_I Reflected $E_R = \frac{R-Z}{R+Z}E_I$ Terminal $E_T = \frac{2R}{R+Z}E_I$	No Echo When $Z = R$

have been described elsewhere this one will not be covered in detail. The Linascope is the same size and has the outward appearance of a conventional cathode ray oscilloscope. A 5-inch cathode ray tube is used to display the echo pattern and the usual focus, intensity, positioning and gain controls are associated with it. Two terminals are provided at the rear of the instrument from which connections are made to the line under test. A switch on the panel provides various pulse amplitudes from 1/10 volt to 100 volts. A small pulse amplitude is used on telephone lines, since an undesirable clicking noise is otherwise created in adjacent circuits. However, on power lines the 100-volt pulse is usually used. A range switch provides ranges of 50, 100, 200 and 300 miles by appropriate choice of the sweep velocity. The equipment is protected against accidental surges from the line under test by means of a spark gap and a 2,500-volt 1-ampere fuse across the line terminals. Parallel-T filters are provided across the line terminals to prevent interference from power frequency voltages.

When locating a fault on a power line, the line is first de-energized and grounds are applied at the far end as a safety precaution. The Linascope is then directly connected to the line. There is a slight advantage in connecting both Linascope terminals to phase conductors, but one terminal is usually connected to a phase conductor and the other to a good ground (towerleg, and so forth). When the Linascope is turned on, the outgoing pulse appears as a vertical pip at the left side of the cathode ray sweep. The echo from the far end of the line usually appears toward the right end of the trace. The echoes from one or more faults appear at intermediate points along the trace. The distance to a fault is measured by using a calibrated mileage scale laid along the face of the cathode ray tube. The known distance to the end of the line can be used as a check.

It will be noted that the distance measurements are limited in this instrument to the accuracy with which one can read a 5-inch cathode ray screen. In practice this leads to a precision of $\pm 1/2$ per cent of the full scale range. Much greater accuracy can be obtained by using an expanded sweep circuit in which a limited portion of the complete scale is selected, amplified to the full screen width, and examined in greater detail. The unit described before has, however, sufficient accuracy for use under field conditions and has a great advantage in terms of simplicity and ease of operation.

Transient Fault Locator

The fault locator was designed primarily for use on relatively long telephone

Figure 1 (left)-Echo arising from fault near the test terminals

Figure 2. Passage of d-c and wave burst pulses through coupling capacitor to transmission line

and high-voltage transmission lines in locating faults which cause permanent outages until repaired. Tests which will be described later have proved that the unit is able to locate practically any fault within this category.

No tests have been made with the unit on distribution networks as yet. Most distribution networks have so many interconnections that the echo pattern will be quite complicated. It probably will prove necessary to have a chart of the circuit under normal conditions, with which the pattern under the faulted conditions can be compared. Even then, the possibility of several paths of the same length will have to be considered. It is doubtful, too, that these units can be made available in sufficient quantities within a power company, for use as a routine maintenance instrument on distribution circuits.

In performing tests on high-voltage transmission lines, speed in the location and clearing of a permanent fault is all important. Another type of fault which is a more common problem to the system operator is the transient fault. Lightning often flashes over a line insulator, and the subsequent power flow causes a momentary interruption of service. When the circuit breakers reclose, the insulator is sometimes able to sustain the line voltage. The insulator is left in a damaged condition and represents a potential source of further trouble unless located and replaced.

The development of the Linascope has continued with the construction of a unit which may be coupled to a high-voltage transmission line via a high-voltage carrier-type coupling capacitor, rather than being connected directly to a phase conductor. This development makes it possible to install the Linascope in a station, with permanent connection to the line. When a permanent fault occurs the instrument can be used immediately to locate it, avoiding the delay necessitated by direct connection to the line.

The ultimate objective with this unit is to incorporate automatic photographic recording gear and to run the Linascope continuously while the line is in operation. With this unit it is hoped that it will be possible to locate transient faults.

In the construction of the transient fault locator, several problems arise, which have not been treated previously.

1. The shape of the pulse generated by the Linascope must be chosen carefully to ensure a maximum signal through the coupling capacitor on to the transmission line.

2. The frequency spectrum of the pulse must be such as to avoid interference to any carrier power line equipment installed on the same line.

3. The Linascope receiver circuits must be designed to avoid interference from the carrier transmitter, and from any radio frequency noise voltages present on the line due to corona.

4. Any radio frequency radiations from the line must be below tolerable limits set by the authorities.

The pulse commonly used when making connections directly to the line is a unidirectional voltage surge of short duration. In choosing a suitable pulse duration, two factors must be considered.

1. The pulse duration sets the minimum distance from which echoes may be received without interfering with the outgoing pulse. That is, if the pulse is too long, then the echo from a nearby fault will start to return before the outgoing pulse has finished.

2. A narrow pulse contains frequency components over a broad band and hence the pulse width must be chosen with due regard to the available transmission band. A handy rule-of-thumb is that a rectangular voltage pulse T microseconds long contains important frequency components up to $1/T$ megacycles.

In the portable Linascope, the authors chose a pulse width of 25 microseconds as a suitable compromise. Since the pulse travels at a rate of approximately 0.1 circuit mile per microsecond, it is seen that echoes from faults closer than 2.5 miles will interfere with the outgoing pulse. However, upon one occasion a fault was located only 250 feet from the test terminals. The line under test was a telephone circuit some 40 miles long, which had a short circuit fault. Upon inspecting it with the Linascope, the pattern shown in Figure 1 was seen. Consideration of the pattern shows that the fault was 0.5 microsecond away or, roughly, 250 feet.

Other workers have shown that the band width can be minimized for a given pulse width by suitably shaping the pulse, but the authors have found that the choice of neither pulse shape nor duration are critical, when the unit is directly coupled to an open-wire line.

However, when the Linascope is connected to an open-wire line via a high-voltage coupling capacitor as is required for a transient fault locator, the unidirectional pulse has several undesirable features. The carrier type coupling capacitors in general use on high-voltage lines have capacitance values ranging from 0.0005 to 0.002 microfarad. A high-voltage transmission line has a characteristic impedance of about 500 ohms. The internal impedance of the Linascope is also set at about 500 ohms for maximum power transfer and the prevention of near-end echoes. Thus the equivalent circuit of the terminal connection is as shown in Figure 2.

It will be noted in the figure that the rectangular pulse is transformed into two very narrow pulses of opposite polarity, each being about one microsecond in duration. Thus it is impossible to develop a pulse of longer than one microsecond duration on the line. This pulse contains important frequency components up to one megacycle and it is feared that it will give undesirable interference to carrier frequency equipment in the 100 to 200 kc band In addition, the Linascope receiving amplifiers must be designed to cover this wide band and will, in turn be subject to carrier interference and radio noise from line corona.

These considerations led to the study of the other pulse shape of Figure 2. This pulse consists of a short duration burst of radio frequency voltage. A burst frequency of 250 kc has been used and a burst duration of about 25 microseconds. An analysis of the circuit of Figure 2, substantiated by tests on transmission lines have shown that the burst passes through the coupling capacitor without appreciable change in shape. Furthermore, by using a series tuning inductor at the base of the coupling capacitor it is possible to tune out the loss due to the coupling capacitor reactance and obtain the full output voltage on the line.

By suitable choice of the width of the burst and by shaping it slightly, it is possible to minimize the interference created by the burst in the transmission line carrier frequency channel.

A live-line Linascope was constructed in June, 1947, using the wave burst pulse. Experiments which are described later have shown that it can be coupled to a ive line via a high-voltage coupling capacitor as anticipated.

It is planned to fit the live-line Linascope with automatic photographic recording gear and to install it on a high-voltage circuit in the near future. The line that will probably be selected for this purpose is the Leaside–Beauharnois 220-kv circuit, which is 303 miles in length.

This line is fitted with Marconi carrier equipment operating at 172 kc and having a band width of 11 kc. Laboratory experiments show that the wave burst develops sufficiently low interference over this band. Work is proceeding with the design of filters to eliminate carrier interference to the Linascope.

Tests

Equipment of the d-c pulse type described previously was constructed by the

authors in September, 1946. The first tests were performed at that time on the 220-kv circuit of the Hydro-Electric Power Commission of Ontario which supplies power from Beauharnois generating station on the St. Lawrence River, to Leaside near Toronto. The total length of this line is 303 miles. The line was removed from service for the tests and all phase conductors were grounded at Beauharnois. The Linascope was connected between the red phase conductor and ground and the echo pattern observed on the cathode ray tube. An echo was observed from the ground connection at Beauharnois. A series of staged faults were then applied at Martintown and then at Bewdley 247 miles and 67 miles from Leaside, respectively. Red phase to tower, red phase to blue, and blue phase to white faults were simulated, the connections to the phase conductors being made with ground clamps. In each case the fault echo was visible on the Linascope.

It will be noted that there is sufficient coupling between the 3 phase conductors that a fault between white and blue phases is visible even when testing from red phase to ground.

The lines under test ran for the first 20 miles along a right-of-way shared by two other 220-kv lines which were alive at the time. The filtering circuits which are included in the Linascope proved adequate to remove any power frequency interference on the cathode ray tube.

Following these tests the d-c Linascope was assembled in a portable self-contained unit. This unit has been used extensively in the maintenance inspection of open-wire telephone lines operated by the commission. Not only has it been useful in locating open and short circuit faults, but it has also proved sufficiently sensitive to locate such minor faults as high resistance joints impeding but not preventing telephone communication and tree branches fallen across the telephone wires.

On July 26, 1947, tests were made for the first time with the waveburst type of pulse using two carrier frequencies, 250 kc and 1 megacycle. Tests were made also with the d-c type pulse for comparison. These tests were made on a 110-kv wood pole line running from St. Thomas to St. Clair, a distance of 66 miles. It was found that the echoes from the far end of the line as well as from artificial faults applied at an intermediate point were readily visible with both the d-c and waveburst pulses. The Linascope was then connected to the line under test via a high-voltage coupling capacitor. As was expected, it was found that the d-c pulse was considerably reduced (over twenty-fold) in magnitude after passage through the capacitor, whereas by suitable tuning it was possible to obtain waveburst echoes with only slight loss in amplitude. With the 1 megacycle carrier bursts, echoes were apparently set up by each pole structure showing up as a continuous interference pattern over the entire length of line. Grounds at the far end of the ine were nevertheless visible.

Experiments were then made to determine the operating limitations of the Linascope. For this purpose a new line of 220-kv construction from Barrett Chute to Oshawa was well suited. This line was, at the time of the tests, completed over a distance of 54 miles, to a point near Bannockburn, but not yet in service. Tests were made from Bannockburn with all phase conductors earthed at Barrett Chute and with faults of various resistance values applied at Mazinaw Lake, 23 miles distant.

Some of the records from this test are shown in Figure 3. It will be noted that open and short circuit faults are clearly visible, and that in each case an echo from the short circuit at Barrett Chute also appears. These oscillograms are reduced from the 5-inch scale of the cathode ray screen. Figure 3(e) was taken with no fault at Mazinaw and with increased vertical amplification. This record is faulty in that the normally straight horizontal sweep is warped due to overloading of the receiving amplifiers. Nevertheless the relative amplitude and directions of the transposition echoes are indicated correctly.

It is interesting to note that the transposition echoes occur in triplets, giving a short-circuit echo, and open-circuit echo, a very slight echo and then repeating. This sequence arises because the impedance decreases, increases, and undergoes negligible change at three successive transpositions.

The practical limit in Linascope sensitivity was taken to be that fault resistance at which the echo was reduced to approximately the same magnitude as those arising from transpositions. It was found that this condition is reached when a phase-to-phase fault as high as 10,000 ohms is applied or when a phase conductor is cut and a resistance as low as 10 ohms is inserted. From these tests the following conclusions were drawn:

1. The Linascope will detect broken (open-circuited) phase conductors.

2. A phase conductor which is short circuited to another phase conductor, to a tower or to a sky wire can be detected so long as the contact resistance is less than 10,000 ohms.

3. The Linascope is not suitable for locating high resistance joints on power lines. However, joint resistances of 10 ohms and

(c) Scarborough line open, wave-burst pulse
(d) Scarborough line open, d-c pulse

higher do occur on telephone lines and these are detectable with the linascope.

4. The case of a phase conductor fallen to the ground but not broken has not been tested. The resistance to ground is probably higher than ten thousand ohms in most cases and so only a small echo would arise from this factor. However, a considerable discontinuity in the conductor capacitance to ground is introduced, certainly as much as is created at a transposition. Therefore it seems reasonable that an echo of about the same size as that from a transposition should be seen.

The experiments outlined previously paved the way for the first tests on a live line on November 21, 1947. The 110-kv bus at Oshawa was chosen for this purpose. There is one 110-kv circuit running east from Oshawa, the nearest transformer station being at Sydney 66 miles away, and another 110-kv line running to Scarborough 28 miles to the west. There is no carrier equipment on these circuits. The linascope was connected to the base of a 0.001-microfarad coupling capacitor normally used for potential indication at the station. The apparatus at the base of the capacitor was replaced by the waveburst tuning unit.

It was found that echoes could be seen and identified from an open circuit at Scarborough some 20 miles away and from the bus connections at Sydney 66 miles away. It had been feared that radio frequency noise due to corona loss on the 110-kv line would interfere with the Linascope trace, but no difficulty of this sort was encountered even though the carrier pulse was less than 50 volts in magnitude. Two of the oscillograms taken during these tests are shown in Figure 4. It will be noted that the waveburst echoes are symmetrical about the horizontal axis. It is not possible to distinguish open-circuit echoes from short-circuit echoes without expanding the sweep in order to examine the polarity of the initial cycle of the echo burst. This is not usually practicable but the nature of the source of the echo is normally known from other considerations. The upper scale on the waveburst oscillograms is a timing wave having a period of 57 microseconds. With the Scarborough tie line energized, Figure 4(a), the echo from the open circuit at that point is clearly visible. A second and a third echo from Scarborough, marked *2S* and *3S* are seen also. The first echo upon returning to Oshawa has again been reflected by the bus connections at that point and has made the return trip to Scarborough two more times.

When the line to Scarborough was opened, the echo from Sydney 66 miles away then became visible. Sydney transformer station was in normal operation at the time and the echo must be due to the combined effects of switching structure, potential coupling capacitors and bushing capacities. The other echoes on Figures 4(a) and 4(c) have not yet been identified.

The d-c Linascope was connected also through the coupling capacitor to the live line. The results of these tests are shown in Figures 4(b) and 4(d). Small but sharp echoes are visible from Scarborough and Sydney respectively. The large negative "tail" on these records is again due to overloading of the Linascope amplifiers.

Conclusions

An electronic echo-ranging fault locator utilizing a unidirectional or d-c pulse has been described. Tests and operating experience have shown this unit to be a useful instrument for locating faults on open-wire telephone and transmission lines. The condition of the line under test is presented graphically on a cathode ray tube in a manner which can be interpreted easily, and one or more faults can be located with an accuracy which is entirely adequate for field use. Tests to determine the operating limitations of the d-c Linascope show that it is capable of locating any fault causing a permanent outage on an open-wire line. The unit is not sufficiently sensitive to locate high-resistance joints on transmission lines.

Progress in the development of a transient fault locator has been noted. The echo pattern of a live 110-kv line has been studied by coupling the Linascope through a high-voltage coupling capacitor. A waveburst has been considered as an alternative to the d-c pulse. The waveburst suffers a disadvantage in that it fails to distinguish the polarity of an echo clearly. However, the waveburst frequency spectrum can be chosen to minimize interference to carrier equipment on the same line.

Design and construction of the photographic recording equipment for the transient fault locator is proceeding and it is planned to make a trial installation in the near future.

Discussion

F. Noakes, D. J. Evans, and T. K. Naylor (The University of British Columbia, Vancouver, Canada): The work of Leslie and Kidd is of particular interest to us at the University of British Columbia since we have under development echo-ranging fault locators for aero transmission lines and power cables.

With reference to overhead lines, several techniques such as those employing d-c pulses, self-generated surges, and the continuous monitoring with radio-frequency bursts were considered. However, it appeared to us that a damped sine wave of approximately 200 to 500 kc would offer the best solution. In the fault locator under development, the signal monitors the line only during the period of power follow-up current in a flashover.

It is our opinion that photographic methods, as sole method of recording, should be discounted because of the delay in developing the film. We feel the photographic recording should be supplemented by a second tube having an exceedingly long memory. This would provide immediate information for the operators.

In some ways, the location of faults in power cables presents more difficulties than the location of faults on transmission lines. For example the time intervals are much shorter, the surge impedance of cable is about one-tenth of that of an overhead line and the attenuation is greater.

Briefly, the apparatus developed at the University of British Columbia consists of a low-voltage impulse generator combined with a timing device for measuring the interval between the transmission of the initial pulse and the reception of echoes from the discontinuities in the cable. The input pulse approximates a 0 – 0.2 microsecond wave which reaches a peak of about 500 volts when feeding a 50-ohm line.

The impulse generator has a high-power *5C22* hydrogen thyratron which discharges a capacitor directly into the cable. A compact 2-kv power supply recharges the capacitor while the echoes are being received.

The timer or marker pips of the echo pattern are compared on a Cossor split-beam oscilloscope adjusted to produce a single sweep each time a pulse is sent into the cable. As the marker pips, common sweep, and initial pulse are synchronized within 0.002 microsecond of one another, small parts of the trace can be expanded without affecting the relationship between the marker pips and the echoes. Hence the starting of the high-speed sweep can be delayed whenever echoes from distant parts of the cable are to be examined in detail. The

apparatus, exclusive of the oscilloscope, weighs about 37 pounds and consumes 175 watts.

Laboratory tests on *RG8U* polyethylene coaxial cable with a 100-ohm fault, 70 feet from one end, show that the distance to the fault may be determined with an error of considerably less than 1 per cent. Tests have also been made on a 3-conductor oil insulated paper power cable 1,389 feet long with a tap 484 feet from the sending end with the same order of accuracy. Investigation of the power cable shows that several miles of cable may be examined for faults and that attenuation is not too serious.

L. R. Spaulding (Bonneville Power Administration, Operations Branch, Portland, Oreg.): Leslie and Kidd are to be complimented upon their work on the "Linascope." They have contributed greatly to the development of an ultimate design of a fault locator which should incorporate all of the best features of all workers in the field.

At the communications laboratory of the Bonneville Power Administration, in addition to development work on the fault generated surge type of fault locator,[1] we have recently experimented with the application of a single, 1-microsecond 10-kv, d-c pulse to a 230-kv line, through carrier coupling capacitors, during fault conditions. The application of the pulse was delayed approximately two cycles (of 60 cycles), and the reflections from it were photographed from a 5-inch cathode ray tube presentation as a single sweep transient. Also, the subject of coupling to a live line, through carrier coupling capacitors in various combinations, is being investigated.

The work on this method of fault location, together with coupling experiments, is not completed, but, upon completion, might provide material of sufficient importance for a formal paper at some future date. However, the limited number of tests to date have been very encouraging and seem to indicate the following preliminary conclusions, which, we hope, can be fully verified in the near future:

1. The single pulse method will not require the assignment of a carrier channel nor in general will it seriously interfere with existing carrier channels.

2. A single 10-kv, d-c pulse of short duration is easier to obtain than a radio-frequency pulse of the same order of magnitude.

3. A delay of two cycles (of 60 cycles) from the start of a fault seems to be sufficient to permit a 10-kv, d-c pulse to over-ride residual steep wave front voltage wave distortions.

4. Within a two cycle period, a single delayed pulse and the necessary receiving equipment can be switched to the faulted phase, or to one of the faulted phases in the event of a line to line fault, by use of information supplied from conventional transmission line relay equipment, during fault.

5. Switching to the faulted phase or one of the faulted phases appears necessary because better reflections and less attenuation of the signal is experienced this way.

6. Two instead of three carrier coupling capacitors will provide adequate coupling to a 3-phase line by paralleling and pulsing the two coupled phases when the third phase is grounded.

REFERENCE

1. A TRANSMISSION LINE FAULT LOCATOR USING FAULT-GENERATED SURGES, R. F. Stevens, T. W. Stringfield. AIEE TRANSACTIONS, volume 67, 1948 (PROCEEDINGS T8308).

R. F. Stevens (Bonneville Power Administration, Portland, Oreg.): When we at the Bonneville Power Administration (BPA) first started work on this problem of fault location, we did not know what other investigators might be working in the field. However, we felt that the possibilities of applying modern electronic techniques would not long be overlooked. This supposition has been borne out by two papers on the subject presented at the Paris International Conference on Large High-Voltage Electric Systems,[1,2] and by this very excellent paper by Leslie and Kidd.

We are particularly interested in this last paper because the authors have not contented themselves, as some investigators have done, with the location of sustained faults, but have tackled the much more difficult problem of transient fault location.

The paper does not report operating results of the equipment in locating transient faults. I understand that this is because they have not had any such faults on the line to which the equipment was connected. We at Bonneville have gained considerable experience from staged fault tests, in which a line to ground arc was initiated by pulling a fine copper wire into the line by means of a piece of glass twine. Fortunately, the loop arrangement of the BPA 230-kv lines makes such tests possible at one point on the system, even under the present heavily loaded conditions.

The matter of coupling is very important and we would welcome more detailed information in this regard. Is one phase only pulsed, are all three pulsed in parallel, or is the equipment switched according to which phase is faulted? To what phases is the receiving equipment coupled, or is it automatically switched according to which phase is faulted? These questions are important because tests made by BPA have shown that the coupling arrangements most desirable from a standpoint of cost and simplicity will not always give satisfactory results.

We understand that the present equipment installed to locate transient faults pulses the line continuously at all times. Is this to be the standard arrangement? If so, what considerations favor the use of this method in preference to automatic starting of the equipment at the time of the fault?

Some pulsing methods would apparently require permanent assignment of a portion of the carrier spectrum. This would be an important factor in any location where the carrier spectrum is crowded. How broad a frequency band will have to be reserved to avoid interference?

I believe that the feasibility of building a practical and highly accurate locator for transient faults is assured on the basis of results reported. I do not know whether the device which will ultimately be most widely used will take the form proposed by the authors, or one of those Stringfield and I have proposed in our companion paper,[3] or some still different form. Regardless of the outcome, and we are quite open-minded, the work of Leslie and Kidd is an important contribution to solution of the over-all problem.

We have greatly appreciated the opportunity of exchanging information with Leslie and Kidd while their work and ours has been in progress.

3. A TRANSMISSION LINE FAULT LOCATOR USING FAULT-GENERATED SURGES, R. F. Stevens, T. W. Stringfield. AIEE TRANSACTIONS, volume 67, 1948, pages 1168–79.

J. R. Leslie and K. H. Kidd: Stevens has asked for details of the transient installation as now operating. Leaside transformer station is the terminus of four 220-kv circuits ranging from 54 to 303 miles in length, and normally paralleled on the 220-kv bus. The waveburst Linascope is connected to one phase of this system, through a tuned coupling capacitor. Three of the four circuits are provided with relays which initiate the Linascope in the event of a circuit fault. A photograph of the Linascope trace of the faulted circuit is taken by momentarily switching on the Linascope pulse transmitter and brightening the cathode-ray trace. After a one-second interval, a second record is taken which will normally correspond to the circuit when restored to normal.

A transient fault has not occurred on these circuits since the Linascope was installed in July 1948.

The unit may be used visually in case of a sustained fault by connecting the output to the faulted circuit. Routine instructions have been issued to the operators to cover such an emergency.

The relative merits of a d-c or waveburst pulse require further study. Tests with the two pulses definitely indicate that the latter gives considerably greater sensitivity when connected through a coupling capacitor. However this factor may be offset by the greater ease with which a d-c pulse can be generated.

The use of high-speed switching to select the faulted circuit, as suggested by Spaulding, will provide a suitable method of monitoring several circuits when they are not normally in parallel.

It is felt that the use of a repetitive surge offers one fundamental advantage over a single pulse in that a reflection is more likely to occur at the moment of fault current maximum.

Noakes, Evans, and Taylor remark that photographic recording introduces an objectionable delay, whereas the authors feel that most transient faults need not be located immediately. The use of an extremely long persistence screen or of magnetic recording which would allow immediate playback are both interesting alternatives.

A Transmission Line Fault Locator Using Fault-Generated Surges

R. F. STEVENS
MEMBER AIEE

T. W. STRINGFIELD
MEMBER AIEE

THE characteristics of an ideal fault locating device are listed. These are contrasted with those of the methods available in the past. Some method based on measurement of the time required for a wave to travel between the fault and a known point is believed to offer the best chance of fulfilling the ideal requirements. Three systems using this general approach are listed, namely,

1. The "pulse radar" method.
2. The "modulated frequency" method.
3. The "fault-generated surge" method.

The paper describes the development, by the Bonneville Power Administration (BPA) of two different types of fault locator, both of which make use of fault-generated surges. These are called for convenience the type *A* and type *B* fault locators, respectively.

A type *A* fault locator has been in successful operation on the system of the BPA for about a year. This device is generally applicable to high-voltage lines, and is far more accurate than other methods used previously. However, it requires use of photographic film, and, in its present form, considerable experience is necessary for quick and accurate interpretation of results.

The type *B* system is less generally applicable; but, where it can be used, will give an accurate indication or chart record of the distance to the fault in miles, without resorting to photography. This device approaches quite closely to the ideal as defined.

Both the type *A* and type *B* systems are automatic, are designed for coupling to live lines, and will complete their measurements before the fault arc is extinguished. Therefore, unlike most other systems and devices, they will locate those faults (constituting about nine out of ten of all faults) which are not sustained, as well as the smaller number of faults which are.

The possibility is suggested that one of these systems may someday be used as a basis for a fundamentally different and extremely fast system of power line protective relaying.

The problem of locating transmission line faults is as old as the power industry itself. As transmission distances have grown longer, and as more lines have been built through isolated mountain and desert areas, the importance of the problem has grown. Meanwhile, the available fault locating methods have remained very inadequate indeed.

The engineers of the Bonneville Power Administration have for some time been seeking a better solution. One of the steps was to define the requirements for a theoretical ideal fault locator. An attempt was made to build a practical device to meet these requirements, or to approach them as closely as possible.

Requirements of the Ideal Fault Locator

The requirements of the ideal device were established as follows:

1. It should complete its measurement before the fault arc is extinguished. (In this way it will locate faults which are not re-established when the line is re-energized but which may, nevertheless, have caused damage.)

2. It should be able to locate a fault to the nearest tower or span. (Accuracy of the order of $\pm 1/10$ mile.)

3. It should be designed for installation in an accessible spot (preferably an attended substation at a line terminal).

4. It should not require slow and cumbersome work, such as developing photographic film, before answers are available.

5. Results should be in a form which can be interpreted readily by any station operator or line foreman.

6. Equipment should operate with safety to personnel and service.

7. Equipment should be simple, rugged, and relatively inexpensive.

Limitations of Previous Methods

The contrast between these requirements and the capabilities of past methods is striking. Patrol of an entire line from the ground is extremely slow, and does not always locate the point of fault. Patrol by air (slow plane or helicopter) is faster but limited by weather and terrain, and by availability of aircraft at time of fault.

Sectionalizing switches, by isolating a sustained fault in a line section, simplify the problem but do not solve it, since the faulted section must still be patrolled. Moreover, unless the switches are attended by operators, or carrier-supervisory-controlled (expensive in either case), valuable time will be lost before they can be operated. This method is of no help where the fault is not sustained.

Another aid, the commercially manufactured annunciator ammeter, is useful, but it has an error of 15 or 20 miles or more under unfavorable conditions. Precision is limited because the current is measured in steps and because of variations in tower footing resistances. A further disadvantage is that system connections at the time of fault must be considered. (To overcome the first of these limitations, BPA has developed a modified ammeter with a continuous scale

R. F. Stevens is chief, design section, and T. W. Stringfield is communication engineer, Bonneville Power Administration, Portland, Oreg.

The authors wish to express their appreciation to L. R. Spaulding and W. V. Behrens in this acknowledgment of their suggestions and work in the design, construction, and test of the equipment; also, to M. G. Staton and his associates at the Radio Corporation of America for suggestions regarding the directional coupling device.

Figure 1. Type A fault locator, model number 1

which is actuated by a charge stored in a capacitor by the fault current and proportional to its magnitude.)

Another device,[1] developed by BPA, is the use of an iron core magnetized by the fault current. After the fault, the degree of magnetization is measured. Other devices, including electronic devices, have been developed commercially to aid in locating faulty insulators while patrolling the line. Each of these methods, however, is lacking in one or more of the important characteristics desired.

Traveling Wave Methods

All experience to date seems to indicate that the best hope for a better fault locator lies in the use of some method for measuring the time for a wave or pulse to travel between the fault and a fixed reference point. This has also been suggested in a paper[10] by K. Berger.

The systems which use this principle can be divided into three main categories namely:

1. *The Pulse Radar Method.* This uses a pulse of high-frequency oscillations (or a d-c surge) artificially generated and impressed on one end of the line. It travels to the fault, from which it is reflected back to the source. One half the time of round-trip travel, multiplied by the propagation speed (for practical purposes, the speed of light) is equal to the distance to the fault.

2. *The Frequency Modulated Method.* Here a high-frequency voltage is impressed on one end of the line, from which it travels to the fault and is reflected back to the source. The frequency of the impressed voltage, however, is varied with time at a linear rate. The reflected signal, arriving at the source, therefore, will have a different frequency than the frequency being transmitted at that same instant. The difference in these frequencies is measured and is proportional to the distance to the fault.

3. *The Fault-Generated Surge Method.* This method uses the surge generated by the collapse of voltage at the fault itself. Two systems have been developed for the application of this method and, for convenience, are designated as the type *A* fault locator and the type *B* fault locator.

A. In the type *A* system, the surge from the fault travels to a station at one end of the line, where it starts a timing device. It is reflected from the station bus, back down the line to the fault, where it is reflected, and it again travels to the station. The time interval between the first and second arrival of the surge at the station is measured by the timing device, and is proportional to the distance to the fault.

B. The type *B* locator system makes use of both of the surges which originate at the fault, and which travel down the line in opposite directions. One of these arrives at what may be called the "near end" of the line, and triggers a timing device. The other travels to the "remote end." On arrival there, it causes a broadband radio transmitter to send out a timing pulse, which is received at the near end of the line and used to stop the timing device. The elapsed time interval (less a constant correction for the difference in length between the path through space and the path along the line) is a measure of the distance to the fault.

The Pulse Radar and Frequency Modulated Methods

Most of the work done by other investigators[2–9] has been based on either pulse radar or frequency-modulation (FM) methods, and some success has been reported.

However, in order to meet the exacting requirements for the ideal fault locator previously set forth, it was decided to concentrate on other approaches to the problem. This was because of the following difficulties anticipated in the application of the pulse radar or FM methods:

1. High cost of equipment for generating, and impressing on the line, through a suitable broadband coupling, the artificial pulse.

2. Difficulty of obtaining the desired precision with a carrier of frequency sufficiently low for transmission along a power line.

3. Obscuring of the relatively weak artificial pulses by the far stronger pulses originating at the fault itself and by successive reflections of such pulses.

These objections are less valid if use is limited to location of sustained short circuits, or open circuits, on dead lines. Additional study may also overcome some objections to use on live lines. For instance, it might be practical to delay sending out the artificial pulse long enough for the initial transients from the fault to be greatly attenuated, yet not long enough for the arc to be extinguished.

The Type A Fault Locator System

Concern over the effect of fault-generated surges in masking signals under the pulse radar system led to the idea of using these very surges themselves as a means of measurement. This resulted in development of the type *A* system shown diagrammatically in Figure 1.

In this diagram (1) is a transmission line connecting two substations (5) and (6). Let us assume that a phase-to-ground short circuit occurs on this transmission line, represented as a resistance to ground (4). The line voltage at this point, collapsing suddenly from a value expressed in tens of kilovolts, to a lower value, causes traveling waves (41) and (42) to move along the line in opposite directions from the fault. When wave (41) arrives at bus (5), it is picked up by capacity coupling (8), which is of the order of 15 micromicrofarads. Resistor (11) in conjunction with capacitor (8) will be recognized as a differentiating cir-

Figure 2. Coupling device

Figure 3. Control amplifier

Figure 4. Type A fault locator

cuit or high-pass filter, passing only the steep-wave front of a traveling wave, and resulting in a sharp pulse of short duration being fed into pulse amplifier (14). Resistor (13) is used to terminate coaxial line (9) in its surge impedance. Resistor (11) is very much larger than resistor (13) and the two together step the voltage down to a low value. The traveling wave may be either negative or positive in polarity, depending on the instantaneous line voltage at the time the fault occurs. However, it is desired in this case to display this pulse on the indicator screen in an upward direction with respect to the X-axis, regardless of the surge polarity. This avoids confusion with range markers. Therefore, the output of the pulse amplifier (14) is fed into a conventional phase splitter (15), the output of which is fed in turn into a conventional full-wave rectifier (16) connected for negative output. Hence, regardless of polarity, the polarity of the pulse emerging from the rectifier tube is always the same.

The pulse output of the rectifier is fed into two separate paths. The first path provides the input of the Y-axis plates of a cathode ray oscilloscope. The second path provides the trigger which initiates the horizontal sweep. In the first path, the pulse is fed into a conventional pulse amplifier (17), thence into a cathode follower (19) which overdrives a remote cut-off type pentode (20) and sets the grid leak bias in accordance with the magnitude of the first pulse. The gain thus varies inversely with the magnitude of the first pulse and is set for the duration of the sweep. The output of the signal biased amplifier is then inverted and amplified in inverter amplifier (21). From here it is led to the Y-axis input of cathode ray tube (25) to furnish upward deflection of the scope trace. In the second path, the negative pulse output from tube (16) is fed into inverter amplifier (18) which triggers the thyratron switch tube (24). The output from the cathode resistor of (24) triggers the oscilloscope which then produces a single high intensity sweep.

Meanwhile, the surge (41) which started this train of events is partially reflected from the substation bus. It travels back toward the short circuit, where it is again partially reflected back to bus (5). On this second arrival, a pulse is again fed to the Y-axis deflection plates, producing a second pip on the trace. This second pip is displaced from the first pip a horizontal distance proportional to the round trip travel time of the surge between bus (5) and the short circuit (4).

Wave (42) in the meanwhile has traveled to the far end of the line where it is partially reflected at bus (6) and travels back to substation bus (5) causing a third pip which is displaced from the first pip a horizontal distance proportional to the round trip travel time between the fault and bus (6). Wave (42) returns through the fault point by induction into the unfaulted phase conductors and through the fault itself since the tower footing resistance is usually appreciable. Since the identity of the pips produced by waves (41) and (42) is ambiguous, the fault may be at either of two locations depending upon the interpretation. However, experience to date (though very limited) indicates that the wave (42) reflected, from the far end of the line, usually produces a steeper pip and of somewhat greater magnitude than that for the wave reflected from the fault and this may be of considerable use in proper identification. Annunciating ammeters also furnish supplementary information as to in which half of the line section the

fault occurred. The foregoing does not apply to phase-to-phase faults where, because of the low fault resistance, wave (42) for practical purposes does not penetrate through the fault and thus does not produce a pip.

The oscilloscope is provided also with a calibrated range marker circuit which produces downward pips at intervals of ten line miles, enabling the fault distance to be read directly with reasonable accuracy. Since the trace is nonrepetitive, and persistence of the screen is limited, it is necessary to photograph a single trace. This is done by means of a 16 millimeter movie camera (29) which has its shutter always open and which views the cathode ray tube face through light shield (31). Thyratron switch tube (24), when fired, operates relay (27), the armature of which strikes a button (28) on camera (29) causing a new frame to rack up. Thyratron switch tube is reset by reset tube (25) which operates relay (26), momentarily opening the contacts (23), breaking the plate current to (24). Fogging of the film due to heater glow in the cathode-ray tube is reduced by a suitable light filter (37), by tilting the camera and also by racking up a new frame once an hour by means of a trigger produced by a synchronous motor-driven switch (38).

The used film is automatically stored in a light-proof container attached to the camera and readily removable. This container is a daylight developing tank, means being provided to introduce developer and fixer. After developing and fixing, the film is dried and viewed through an enlarging viewer in order to read the fault distance.

Recording of the time of the various photographs is done by means of an argon lamp (34) which is flashed by the voltage surge across the operating coil or relay (27). This momentarily illuminates the clock face (36) which is in view of the camera and records the time on the film before the next frame is racked up.

Operation of the equipment may be checked by means of a test unit which simulates a short circuit by furnishing two successive pulses, the magnitude and spacing of which are adjustable. The sweep trace may be viewed through peep (33) in the light shield.

Description of Equipment

Figures 2, 3, and 4 show the various units of the fault locator. These include a voltage coupling device with the necessary coaxial cable, a control amplifier unit, an indicator, and a camera. The coupling device shown in Figure 2 is inexpensive and simple. It is merely a piece of one-inch pipe about four feet long supported in a horizontal position parallel to and beneath the bus. Incorporated into the support is an insulating tube inside of which is the resistor of the differentiating circuit. In the experimental equipment, the support itself was a portable pipe tripod with a pipe extension and micarta tube. In a permanent design, one of the regular bus support pedestals might be used. Coaxial cable is used to connect the coupling unit to the control amplifier unit (Figure 3) normally mounted in the substation control house.

A standard test oscilloscope manufactured commercially was used as an indicator in the first model. Essentially, the indicator unit must provide a driven sweep, a high intensity trace, a wide-band video amplifier and a range marker circuit.

Minor modifications were made to the oscilloscope circuits, and, in addition, the control amplifier was provided, to receive the input signal and shape and amplify it to the proper level, and to control and synchronize the functioning of the equipment. If there should be occasion to produce this equipment in quantity, the indicator and control amplifier would doubtless be combined in one case, and some of the unneeded features of the present oscilloscope would be omitted.

Operating Experience

In Figure 5 is shown the BPA 220-kv system on which the first fault locator was tested and is presently installed. In Figures 6, 7, and 8 are shown oscillograms for staged single phase-to-ground short circuit tests on the J. D. Ross–Chehalis 220-kv line. The line was connected to the system at J. D. Ross only, being open circuited at Chehalis during the tests. The short circuit was applied by pulling a fine wire, grounded at one end to the tower, into the line conductor. The fault tests for Figures 6 and 7 were the first short-circuit tests made using the type *A* fault locator and the distances to the faults were unknown to the operators. The distance to the fault was determined, within an error of one mile, from the

oscillographs in each case. During these tests, the signal was fed directly into the oscilloscope Y-axis so that positive and negative surges could be distinguished. In Figure 8, the fault distance was known beforehand, the purpose of the test being to check the operation of the signal biased amplifier which sets the gain for the sweep duration. Figure 9 is a lattice diagram,[11] for the fault shown in Figure 8, and together with Figure 5 is a means for showing the time of arrival of the waves producing the pips.

Figures 10, 11, 12, and 13 are oscillograms for line faults obtained under service conditions with the type *A* fault locator installed at Spokane, Wash. Unfortunately, from the standpoint of gaining data and experience, lightning trouble in the Spokane area was unusually light during this season. Practically all of the strokes occurred on the line sections beyond Grand Coulee which is considered the range of the type *A* fault locator. However, several of these faults were successfully located.

Figure 10 and Figure 11 are oscillograms for faults occurring 24.1 miles from Columbia and 31.5 miles from Coulee, respectively, on the Coulee–Columbia line, and were successfully located even though they occurred in the next line section and at a distance beyond the normal range of the instrument. This is possible because of the length of line (82 miles) between Spokane and Grand Coulee in effect cancels out for the initial wave and the waves reflected from the fault and Columbia, since these are delayed by the time required to traverse the Grand Coulee–Spokane line section. On this basis, the oscillograms were interpreted as if the fault locator were installed at Grand Coulee instead of Spokane.

Figure 12 is an oscillogram obtained for a phase-to-phase fault on the Spokane–Coulee line and caused by arc-over when the conductors whipped on ice unloading. This occurred at 72 miles from Spokane, according to the oscillogram, but no damage was found on a quick inspection of the line. The icing conditions on the line were most severe for several miles at this distance, and also, the annunciator ammeters indicated the fault to be in that neighborhood. A total of five such faults occurred within a half-hour period at approximately the same distance and were similarly recorded. A careful scrutiny of the conductors for burns has not been made to date.

Figure 13 is an oscillogram obtained for a lightning stroke on the Columbia–Midway line. Due to the fact that the location of the fault locator was at Spokane, the interpretation of this oscillogram is difficult because of the Coulee–Columbia–Midway loop. On the basis that the initial wave could travel directly from the fault to Spokane over two paths and that the first to arrive triggered the sweep and the second to arrive caused the oscillations beginning at 11 miles, it was deduced that the fault occurred at 28 miles from Columbia. The remaining pulses could then be accounted for on the basis of reflections using a lattice diagram (not shown). The annunciator ammeter indicated the fault at 0 to 26 miles from Columbia. A search for damage from this fault has not yet been made.

Improvements in Second Model

The purpose of the first model was to prove the feasibility of the basic method, and no attempt was made to achieve extreme refinement or precision. Methods by which this could be done will not be discussed in detail, as they will suggest themselves to any engineer familiar with radar techniques. Some of these are exemplified in the number 2 model which is being designed for monitoring the 167-mile 230-kv line being constructed from Grand Coulee to Snohomish, Wash.

Figure 14 is the block diagram for this model, and Figure 15 shows the type of signal presentation used.

By making the sweep circular, it is possible to increase its length by a ratio of

three to one. Range markers are not displayed on the same trace as the signal, but on a separate concentric trace of slightly smaller diameter. These factors, together, make it practical to provide range markers at intervals of one mile as compared to ten miles in the first model.

It is proposed to use a crystal controlled oscillator for range markers. A lower frequency (possibly supplied by count down from the range mark oscillator) will supply sine and cosine waves, to the X and Y axis plates respectively, to generate the circular sweep.

In this model, the signal pulses are displayed inward or outward from the trace, according to their actual polarity. This is an aid to identification of the signals. It is feasible because the range markers are displayed on a separate calibration trace. The phase splitter and rectifier, though removed from the main signal path to the oscilloscope, are retained to provide the positive pulse to set the signal-controlled gain.

Another proposed improvement, to be developed, is a directional coupler which will accept only incoming surges from the line to be monitored. Such a device, if successful, will eliminate most of the larger spurious reflections. Two methods have been suggested. One involves use of an additional electrostatic coupling to the line several hundred feet from the station. The other involves use of a shielded electromagnetic coupling in conjunction with the electrostatic coupling previously described. Outputs will be adjusted to the same level and combined in such a way that they will add for an incoming, and cancel for an outgoing surge.

Application of Type A Fault Locator

For a complete application to a large power system, it is intended that one type A device will be installed at each major substation, with an electrostatic coupling device positioned under the

Figure 14. Type A fault locator, model number 2

Figure 15. Cathode ray tube presentation for type A fault locator, model number 2

Figure 16. Type B fault locator

middle phase of the bus. In this position, the equipment will record a fault occurring on any phase, of any line radiating from the substation. While the equipment itself will not discriminate between lines or phases, this information is available from the regular indicating lamps and relay targets.

The fact that a single instrument will record faults on all lines connected to a given station has the advantage of minimizing the amount of equipment necessary.

An alternate arrangement may be found desirable, though more expensive, if a successful directional coupler can be built. This would involve one fault locator coupled to each line.

In either case, installation of locators at opposite ends of important lines will be useful in providing a double check on the fault location.

Advantages and Limitations of the Type A Fault Locator

The device has the following advantages:

1. It is far more accurate than any method in common use.

2. It operates before the arc is extinguished and thus measures the distance to nonsustained faults.

3. It is safe.

4. It is relatively inexpensive. The cost is highly variable depending on number manufactured and refinements provided. In any event, it would probably be only a fraction of the amount which would be spent for sectionalizing a long 230-kv line.

The principal limitations of the type *A* fault locator are the presence of spurious pulses, the requirement for taking photographs and developing film, which is comparatively slow and cumbersome, and the training required for correct interpretation of the records.

If it were possible to build into the equipment the necessary brains to discriminate with certainty between the true and spurious pulses, then it would be possible to operate an indicator or recorder from which one could read, directly, in miles, the distance to the fault. This would eliminate the need for developing photographic film; it would be faster, and the results could be interpreted by any station operator or maintenance man.

The cost could be decreased because no cathode-ray tube would be required. All that would be needed would be a few simple radio tubes and other components, and the indicator. Perhaps development of a directional coupler, or some method not now apparent, may later make this improvement of the type *A* fault locator possible.

The Type B Fault Locator System

The type *B* fault locator system was designed by engineers of the BPA on the basis of experience with the type *A* system, and is designed to overcome the objections to the latter.

The method of operation, shown schematically in Figure 16, is as follows:

A transmission line (1) connects substations (5), (6), and (7). Upon the occurrence of a fault at point (4), two equal surges will originate. One will travel down the line to the substation (5), where the indicator unit of a type *B* fault locator is coupled to the bus. This traveling wave will be sharpened in passing through the differentiating circuit (8, 11) of the coupling, will be amplified in the pulse amplifier (14), and will then go to the pulse splitter (15) and full-wave rectifier (16), all in the same manner as described for type *A* equipment. The output of the full-wave rectifier will always be a negative pulse. This will be amplified and inverted in the next stage (18). The output triggers a thyratron switch tube (23) which starts an electronic time interval counter (51). Meanwhile, the other surge is traveling down the line in the opposite direction. It eventually reaches substation (7) at the extreme right. Here there is coupled a "remote end unit" of the type *B* fault locator, which includes coupling device, delay line, amplifier, phase splitter, and full-wave rectifier. The full-wave rectifier, as before, puts out a pulse of negative

Figure 18. Proposed type of chart record for Type B fault locator

polarity regardless of the polarity of the original traveling wave. This output pulse is used to modulate a radio transmitter. This radio signal is transmitted either directly or via intermediate radio relay stations to the radio receiver (54) at the other end of the line. The output of this receiver triggers thyratron switch tube (53) which stops the action of the electronic counter (51). The delay line (71) may be a fixed or variable delay to zero the equipment for difference in path length of the transmission line and airline. It may also be installed in the receiver (54) output.

The electronic time interval counter (Figure 17 shows a standard commercially manufactured product) is a decade box consisting of six rows of lamps, ten lamps to a row, and is capable of recording elapsed time in microsecond units up to 999,999. This counter can readily be calibrated in terms of distance to the fault, to the nearest 0.1 mile, consideration being given to the constant propagation time between the radio transmitter and receiver.

The advantages of such an indication as compared to the development and interpretation of a photographic film are apparent. It is merely necessary to log the reading and reset the device ready for the next signal.

If a permanent record is desired, a method has been devised for providing this by adapting a commercially manufactured chart recorder for use with the time interval counter. One type wheel with digits 0 to 9 is provided in the chart recorder for each decade of the interval counter. Each such type wheel is notched ahead in synchronism with a 10-point 2-deck telephone-type selector switch or notching relay. The latter samples in turn each lamp circuit from 0 to 9 of the corresponding decade of the interval counter, or until an energized lamp circuit is found, whereupon the notching action stops. For instance, if lamp number 7 is energized, then the notching relay and the type wheel stop rotation when digit 7 on the latter is in position to print.

This sampling process starts upon arrival of the signal, and stops when the distance to the fault (in miles and tenths) is set up on the type wheels in agreement with the lamp indication. This is then automatically printed on the chart, together with the date and the time of day in hours, minutes, and seconds. Figure 18 shows the type of chart record to be used. The device then resets automatically.

Application of the Type B Fault Locator

Experience gained in the use of the type *A* locator, plus the general information already available from the electronics field, has made it possible to proceed with confidence on designs for the first type *B* fault locator installation (Figure 19).

This will provide monitoring of faults on the lines connecting the Snohomish, Covington, and Olympia substations of the BPA, and will be put in operation as soon as the microwave radio relay links between these stations are completed.

Figure 19 shows a type *B* remote end unit at Snohomish and one at Olympia, and a type *B* indicator unit at Covington. This would make it possible to locate faults occurring on the BPA line between Covington and South Renton, and on city of Seattle Lines between South Renton and Seattle.

When the radio relay communication system is completed south to J. D. Ross, the indicator unit will be moved from Covington to the latter station, from which point it will be able to locate faults anywhere in the 230-kv system between Ross and Snohomish, a total line distance of approximately 170 miles.

It will be seen that the type *B* fault locator equipment is not needed at each end of each line section to give full coverage. Instead, indicator and remote end unit can be placed several hundred miles apart and still monitor the circuits between regardless of the number of intermediate substations.

In addition, it appears that the identical equipment installed to monitor the direct circuits between Ross and Snohomish substations will, at the same time, monitor a total of 534 additional circuit miles of the transmission network, lying mainly in central Washington.

This feature which comes as an extra dividend is most welcome, as the incidence of lightning along these line sections is considerably higher than the general average for the region.

Sections of line accurately monitored by the single fault locator installation are shown in heavy lines in Figure 20. Line sections shown by a narrow line are monitored only to the extent of indicating that the fault is in that section. Furthermore, the points of zero mileage reference for the line sections in central Washington are not Snohomish as is the case for the direct lines between Snohomish and J. D. Ross. However, these zero points may be established readily by a study of Figure 20, remembering that the indicator unit at J. D. Ross is receptive to only one pulse from the line coupling and only one pulse from the radio receiver, and whichever arrives first starts the time interval counter and the second to arrive stops it. In order to facilitate identification of the fault location, charts will be provided for each line giving tower number versus mileage as indicated by the fault locator. The identity of the line section involved would be provided by knowledge of circuit breaker operation.

Experience with the type *A* fault locator leaves little doubt that surges traveling the longer distances from faults in central Washington will arrive with sufficient amplitude to operate the equipment. To what extent precision of measurement will suffer from flattening of the wave front as the surge travels the greater distance remains to be shown by actual test.

It is expected that surges from switching at intermediate stations will operate the equipment, providing valuable calibration points without the necessity of staging fault tests.

With the future extension of the microwave communication system, it will be possible to add additional fault locator equipment which will remove the areas of ambiguity and provide accurate monitoring of faults on all portions of the main transmission network.

Economies of the Type B Fault Locator

It should be said that the type *B* locator can only be applied economically under certain special conditions. Specifically, it requires a broadband radio link between the two ends of the line. Power line carrier might perhaps be used at considerable sacrifice in precision.

The cost of a radio link for fault location alone would generally be prohibitive. However, there are likely to be many places where such a link will be installed for other purposes. The BPA, for instance, had under way plans for a multiplex microwave radio link system with channels available for communication,

telemetering, facsimile, relaying, and supervisory control to all its major substations. This system was planned for these basic uses, without, originally, any regard to its possible use for fault location.

It is believed that in time many other power utilities will find it to their advantage to make similar applications of radio relay for communication, telemetering, and the like. Such action is likely to be hastened by overcrowding of the spectrum suitable for power line carrier, as well as cost advantages of radio for multichannel use. Such a system can be adapted at nominal cost to fault location without interference with its primary functions.

Where the utility does not wish to develop its own radio links, it may be well to explore the use of microwave links owned by others. Such links are being planned in increasing numbers by telephone and telegraph companies, radio manufacturers, and broadcasters. Fault locator signals are transmitted for less than ten microseconds. Compared to this, 2,000 microseconds are required for transmittal of one cycle of a 500-cycle audio tone, and about 30,000 microseconds are used for transmittal of one television frame. Obviously, a ten microsecond interruption to either sound or television transmission would not be perceptible.

Advantages of Type B Locator

It is believed that the advantages of this equipment are apparent.

1. Cost, exclusive of the radio link, is small. The units at each end require only inexpensive radio tubes and components. No camera or cathode-ray tube is required.
2. Readings are instantaneous.
3. Readings can easily be interpreted by any operator or maintenance man. No special skill or training is required.
4. No delay in developing of film is required.
5. Devices of the type described can be installed at points several hundred miles apart and monitor the lines in between, regardless of the number of intermediate stations. This results in decreased cost, and a chance to put the indicator at a central operating point.
6. This type of equipment is not subject to ambiguities because of multiple reflections. The direct surge will always arrive first, will trigger the equipment, and any subsequent signals will be rejected. Sufficient amplification, therefore, can be used to insure positive operation of an indicator or recorder.

General Factors Affecting Operation, Attenuation and Reflection

All traveling wave methods require that attenuation and distortion be sufficiently small to permit accurate measurement of time of travel.

In addition, the pulse-radar frequency-modulated and type *A* locator systems require that the coefficient of reflection at the fault be high enough to give a useable reflected signal. In particular, it should be appreciably greater than those from transpositions along the line. This is not a requirement for the type *B* locator, which does not make use of any reflections.

In addition to both of the foregoing requirements, the type *A* fault locator also requires a high coefficient of reflection at the bus itself. Such a condition almost invariably exists. None of the other systems makes use of reflections from the station bus.

Attenuation

Based on well-known theoretical considerations,[7] a traveling wave with a nearly rectangular wave front on a typical 220-kv line would be attenuated to approximately 60 per cent of its initial value after traveling 100 miles on the assumption that there are no corona losses, no leakage conductance, infinite earth conductivity, and that the line resistance is corrected to a frequency of one megacycle. This indicates that a traveling wave generated by an arc-over may be useable for precise range measurement even after traveling several hundred miles or more. The crest voltage of a wave generated by arc-over would be less than normal line voltage and therefore corona and distortion caused by it would be absent. In the case of a surge caused by a combined lightning stroke and power arc-over, only that portion of the leading edge of the traveling wave below the corona voltage would be used for measurement. However, the unpredictables involved in a lightning discharge would enter and recourse must be had to the accumulation of service data by actual installations to determine the practicability in this case.

Reflection from Line to Ground Fault

The surge impedance to ground at an arcing fault to tower is made up of the arc surge impedance, tower surge imped-

Figure 19. Proposed initial installation, type B fault locator

Figure 20. Use of single type B fault locator installation to monitor complex transmission network

ance and tower footing surge impedance to ground, including counterpoises and driven rods, if used. The arc impedance may vary from less than 10 ohms to several thousand ohms, decreasing with current magnitude and increasing with arc length.[8] Consideration of this may be of importance in a pulse-radar type of fault locator which employs a pulse generated at the far end of the line, where the application of the test pulse is delayed for the purpose of allowing surges produced by the fault to attenuate. If the test pulse arrives at the fault when the 60-cycle current is near or at zero, an inadequate reflection may be obtained for measuring purposes. On the other hand, where the fault surge itself is used, as in the type *A* fault locator herein described, it seems reasonable to assume that the arc current will be sufficiently established and the arc resistance low to provide a high-reflection coefficient.

The tower surge impedance is assumed to be of the order of 75 to 150 ohms.[9] This, together with the tower footing resistance, will influence the slope of the front of the initial surge and all surges reflected from the fault, to some degree. However, because of the short physical length of the tower, it seems reasonable to assume that the successive reflections between top and bottom of the tower will probably decay to a low value within one microsecond. It is felt that the effect of tower surge impedance can, for the time being, at least, be neglected. Referring to several of many investigations on lightning reported in the literature,[10–13] these papers give data showing that the surge impedance of tower footings varies with current, and that the ratio of surge impedance to meggered resistance varies from unity to as little as 0.005. For the purpose of estimating the reflection coefficient for a ground fault at a tower, it is safest to assume that the tower footing surge impedance is equal to the meggered tower footing resistance.

Much has been published with regard to the nature of traveling waves caused by lightning on transmission lines, including oscillographic studies, and it is impracticable to give a complete bibliography. Referring to references[14,15] it may be seen that the wave fronts of such traveling waves would, in general, allow their use for fault locating purposes.

Reflection from Phase-to-Phase Fault

With phase-to-phase faults, of which five were recorded during system disturbances, it appears that the fault resistance is very low and the fault has a reflection coefficient practically equal to unity. Figure 13 is the oscillogram for such a fault. It will be noted from this oscillogram that there is no evidence of a reflection from the Grand Coulee bus on the far side of the fault. A defect in the cathode-ray oscilloscope circuit caused the first range marker to occur very nearly at the beginning of the sweep for this oscillogram.

Reflections from Station Bus

A fundamental requirement for the successful application of the type *A* fault locator is that the fault and the substation bus at which the fault locator is installed have a sufficiently high-reflection coefficient for a steep front wave. This condition would be fulfilled if the surge impedance at the fault and the substation bus is much lower than the surge impedance of the line. Furthermore, the reflection coefficients for discontinuities in the line such as transpositions, river crossings and line crossings should be small compared to the aforementioned reflection coefficients. The results of approximately ten tests with single phase-to-ground arcing faults at various tower locations on the J. D. Ross–Chehalis line indicate that spurious reflections due to line transpositions and river crossings are negligible. However, the surge impedance to ground at the faults was considerable as evidenced by the fact that the surge reflected from the far end of the line was transmitted through the fault (see Figures 7, 8, and 9). As a result, the reflection from the fault itself was not as great as hoped for. Substation busses have a high reflection coefficient due to the capacitance to ground of the bus itself and the associated equipment such as circuit breakers and transformers. If several or more lines terminate at the bus, the reflection coefficient is influenced still further. For a discussion and mathematical treatment of the theoretical behavior of traveling waves on transmission systems, the reader is referred to two papers by L. V. Bewley.[17,18]

False Operations

An unknown factor, at the start, was the number of false operations that could be expected from extraneous surges originating from remote portions of the Bonneville and interconnected systems due to switching and induced voltages from lightning. For this reason, a 16 millimeter movie camera with a 100-foot film capacity was chosen so that the number of such operations could be monitored. It was found that, while switching surges originating as far as 300 miles distant were identified as causing automatic operation of the equipment, the frequency of such operations was not excessive, for this type of application.

False operations do, however, constitute a major problem to be overcome in any possible future application of these methods to power line relaying, as discussed later.

Precision to be Expected

The precision of measurement depends primarily on the steepness of wave front if it can be assumed that the speed of propagation along the line remains constant. The electronic equipment itself is inherently capable of allowing far greater precision of measurement than the desired ultimate which is identification of the tower involved. If it is assumed that the surge travels with the speed of light, then a round-trip mile would correspond to 10.74 microseconds. In order to read distances to a precision of ±1 mile, the pulse derived from the leading edge of the traveling wave should have a rise time of approximately this order of magnitude. Tests to date indicate that this order of precision is easily accomplished and encourage efforts to extend the precision to ±0.1 mile to allow identification of the tower at or nearest the fault.

Errors due to variation in the speed of propagation will probably be encountered. Berger[19] reports measured values of 291 miles per microsecond, ±3 per cent as compared with 300 miles per microsecond in vacuum. The effects of ice and variation in earth resistance have still to be determined.

Coupling

Either voltage coupling or current coupling to the line may be used. In either case, the circuit constants of the coupling circuit are selected to provide a high pass filter so that only a small portion of the leading edge of the traveling wave is passed. A pulse of, say, approximately two to five microseconds' duration is thus obtained, the leading edge of which is used for measuring purposes. The 60-cycle component is, of course, almost completely rejected by this type of coupling. Preliminary tests have indicated that existing coupling equipment such as capacitor-type bushings with voltage taps, and even iron core current transformers may be successfully used.

Interpretation

With the type *A* fault locator, it has been found that the interpretation of a

recorded oscillogram is aided by comparison with a test oscillogram obtained by operating the line circuit breakers. On single phase-to-ground faults, the initial surge reflected from the bus at the far end of the line is usually distinguishable because of its greater magnitude and steep front (based on present knowledge) and its position along the base line is a measure of the distance between the fault and the far end of the line. The reflection from the fault itself may then be found at a distance corresponding to the distance between the fault and the substation at which the fault locator is installed. Also, if the first mentioned pulse is not readily distinguishable, then the oscillogram is inspected for two pulses the sum of whose base line distances equals the distance of the line section between the two substations. Approximate distance to the fault as obtained from annunciating ammeters is a further aid in establishing identity.

Relaying

Use of one of the fault-generated surge methods (especially the more positive type *B*) has been suggested for power line relaying.

To date, this has been explored by the writers in a preliminary way only. Many obstacles are apparent. Nevertheless, the method is the fastest conceivable way of determining where a line fault exists. As such, its possible application to line relaying constitutes an interesting challenge.

Discussion

J. R. Leslie and K. H. Kidd (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): The pulse method of locating faults on transmission lines is attracting wide interest, as evidenced by a number of papers presented by various workers. Stevens and Stringfield are to be complimented for undertaking a fresh approach to the problem, that of using the surge generated by the fault instead of applying a pulse from an external source.

The research division of the Hydro-Electric Power Commission of Ontario is engaged in the development of the Linascope, a pulse-type fault locator for locating transient as well as sustained faults, as described in a companion paper.[1]

The writers feel that the Linascope has a number of advantages over the fault generated surge (FGS) method. These are outlined in the following paragraphs.

1. The FGS method is subject to limitations regarding its application to sustained faults. If, for any reason, it misses the initial fault surge, it is of no further use in locating the fault. For instance, it cannot be carried to the scene of the trouble and there put to use.

2. The type *A* FGS method gives a record which it is very difficult to interpret. The record is essentially the same as would appear on a Linascope connected at the fault and looking along the line in both directions.

3. The type *A* suffers the difficulties of single transient photography. With the Linascope, a conventional 1/25 second exposure is used.

4. In the type *A* method, the significant fault pulse undergoes two reflections, one from the station bus and one from the fault itself. The Linascope has only the latter reflection. In addition, for similar conditions, the type *A* pulse travels 50 per cent further than the Linascope pulse.

5. The pulse generated by the fault is likely to be highly variable in magnitude and steepness. The Linascope pulse applied to the line is constant and not subject to this variation.

6. The FGS method has an advantage in that it makes use of a greater pulse magnitude than does the Linascope. However, the present Linascope pulse amplitude of several hundred volts is adequate to show up transpositions, over more than 100 miles of line, which is the limiting sensitivity for either method. Furthermore, it will be quite feasible to increase the Linascope pulse to 10,000 volts or so (only turned on when fault occurs), if necessary.

7. The type *B* locator certainly offers the ideal, simplified form of presentation, but the cost will be prohibitive except in special cases. Care will be needed to prevent incorrect operation from spurious impulses.

8. The Linascope operation can be checked at any time on the live line.

The criticisms of the external pulse method offered by Stevens and Stringfield are not justified. The cost is not out of line with other proposed methods. A major item is the high-voltage coupling capacitor which can be shared with carrier equipment, if desired.

A precision of 1/2 of one per cent of full scale on 25 to 300 mile ranges has been obtained with existing equipment and this is considered to be adequate. It is hoped that interference from the fault generated surge will be avoided by providing a time delay of about ten milliseconds before taking the record. It has been stated that the Linascope pulse may reach the fault at a current

zero and hence not "see" the fault. However, since the Linascope pulse is repetitive (about 200 per second), several pulses will certainly arrive while the power frequency fault current is high.

REFERENCE

1. THE "LINASCOPE"—AN ECHO-RANGING TYPE FAULT LOCATOR FOR HIGH VOLTAGE LINES, J. R. Leslie and K. H. Kidd. AIEE TRANSACTIONS, volume 67, 1948, pages 1162–67.

Richard F. Stevens: The following is an answer to the various questions raised by Leslie and Kidd.

1. It is true that the fault generated surge method cannot locate a transient fault if it misses the initial surge. However, any system which attempts to locate a transient fault will fail unless its action is completed within the fraction of a second before the arc is extinguished. If equipment is carefully designed and maintained, a failure coincident with the transmission line fault seems quite remote. In the case of a sustained fault, another chance for a measurement exists when the circuit breaker is reclosed.

2. We agree that some of the oscillographs published with our paper are difficult to interpret. However, recent tests indicate very considerable improvement can be obtained by changes in coupling methods. Changes proposed for the model 2 (separate range-marker trace, use of longer circular sweep, and display of positive and negative pulses on opposite sides of the base line) will also aid interpretation.

3. The photography of a single transient has not proved particularly difficult. Remarkably good results have been obtained with the f/1.9 lens of our standard 16 millimeter motion picture camera. However, we feel that somewhat better results could be obtained with a faster and more expensive lens. Repetitive traces with a 1/25 second exposure as proposed for the automatic Linascope would no doubt allow the use of a more inexpensive lens. Our main objection to the type A has not been the difficulty of photographing of a single transient, but the fact that it is necessary to wait for the development and interpretation of the film.

4. The fact that the significant fault pulse undergoes two reflections is an apparent disadvantage of the type *A* fault generated surge system. However, the coefficient of reflection at a substation bus is found to be quite high. Our main difficulty is getting a sufficient reflection from the fault arc itself. If the reflection from the substation bus at the far end of the line, instead of the second reflection from the fault, is used, only one reflection of the pulse is involved. In the type *A* fault generated surge system, good results have been obtained in this manner on phase-to-ground faults. Experience would indicate that the 50 per cent additional pulse travel required by the fault generated surge system would not greatly affect the precision of measurement.

5. It is true that the pulse generated by fault is likely to be highly variable in magnitude and perhaps also in steepness. However, the voltages involved are so tremendous that the chance that the pulse would be too small in magnitude is very remote. All pulses measured to date have been so very steep that precision should not be appreciably affected by any variation in steepness. However, the magnitude variation did raise a problem in the design of the equipment to provide proper gain setting for display of reflected pulses. This was solved by designing the circuits so that the gain is a function of the magnitude of the original pulse.

6. We agree with Leslie and Kidd that it is probably quite feasible to apply sufficiently high voltages for proper operation of the Linascope method on transient faults.

7. The discussion recognizes the advantage of the type *B* locator in the form of simplified presentation, but mentions that the cost will be prohibitive in most cases. This is true, but as mentioned in our paper, we believe that the number of places where channels will exist to which it can be applied at a negligible additional cost will ultimately be fairly large; and that where such conditions exist, the advantages will easily justify its use. The possibility of using transmission lines rather than radio relay system to transmit the timing pulse could well be investigated.

Spurious impulses will indeed operate the equipment and several false recordings will be received for each true fault location signal. Figure 18 assumes this. However, the latter can readily be recognized because it will coincide in time with the line relay operation. If desired, the chart recorder can be built so that relay operation will indicate on the chart.

In our paper we discussed the reasons why we first investigated the fault generated surge system, in preference to others, but did not attempt to rule out the artificially pulse systems. In fact, we suggested how one obvious difficulty (interference from fault transients) might be overcome. This suggestion has since been proved correct in tests reported by Spaulding in his discussion of the paper by J. R. Leslie and K. H. Kidd.[1]

In general, we view the present status of the problem stated in the following paragraphs. We consider the type *B* best, where applicable, because it makes the reading of fault location as simple and accurate as the reading of amperes and kilowatts.

There is also a field for another transient locator, perhaps a type *A*, perhaps a Linascope, perhaps some modification or new development. It will be installed in important lines where lack of a communication channel will rule out the type *B*. Attempts to eliminate photography and substitute indicating instruments should be continued so long as any practical hope of achieving this exists.

Finally, there is a field for a simple portable fault locator for locating permanent faults only, if it can be made cheap enough so it can be used where a permanent transient fault locator installation cannot be justified.

Magnetic Suspension of the Watt-Hour Meter Rotor

H. F. TREKELL

J. H. WRIGHT
MEMBER AIEE

Synopsis: By supporting the weight of a watt-hour meter disk magnetically, a bearing system is achieved free from high-unit pressures and, hence, free from the fundamental cause of wear. The magnetic arrangement employs two concentric magnets of "cunico," the inner attached to the top of the shaft, the outer attached to the meter frame. In a meter having other design innovations co-ordinated with the magnetic suspension it promises to give virtually maintenance-free operation and long life.

THIS paper deals with a meter bearing system, magnetic suspension, which is radically different from those now in use. As a result of new materials and new techniques it is possible to make successful application of a concept which has intrigued designers since the early days of the watt-hour meter. Magnetic suspension offers the possibility of eliminating the high pressure inherent in mechanical bearings, pressure which reaches the order of 200,000 pounds per square inch and is the fundamental cause of wear in such bearings. While many improvements have been made over the years and present-day mechanical bearings give remarkable performance, the fact remains that bearings constitute a major cause for meter maintenance.

Mechanical Bearings

The history of the watt-hour meter is replete with progress and improvement in mechanical bearings. From the beginning the axis of rotation of the disk has been made vertical. In all bearing systems now in use, the lower bearing supports all the weight of the moving system and provides also alignment to maintain radial location of the lower end of the shaft. The lower bearing is made in two forms. In the pivot bearing it consists of a hardened pivot running in a jewel cup of sapphire. In most instances the pivot is attached to the shaft and the jewel is stationary, whereas in other meters an inverted construction is used. In the ball bearing, two cup-type jewels of sapphire are used, one jewel being stationary, the other attached to the shaft, with the hardened ball located between the two jewels.

Figures 1 and 2 illustrate both constructions as used in present-day meters. The top bearing functions only as a guide means and consists usually of a brass or bronze bushing attached to the shaft running on a stationary hardened and polished pin as illustrated in Figure 3. In some cases the pin is made long and flexible to provide a cushioning effect to allow disk vibration without excessive noise. In others, as shown in Figure 3, a vaseline lubricant is used to keep vibration to a minimum. In all cases, small clearances are employed.

Development and improvement of these mechanical bearings to their present state has included extensive investigation of the best in materials and lubricants as well as in the proportioning of parts.[1,2] The use of noncorrodible material for the pivot or ball or materials where any products of corrosion are nonabrasive has contributed to this improvement;[3] so also have superior lubricants[4] to give long life without oxidation, evaporation, and loss by creeping away, and the use of oriented sapphires[5] to take advantage of the best wear properties of the jewels.

These advances have extended bearing life to the point where it is common practice to check meters only once every eight years. However, the urge for improvement is ever present, since reductions in service and maintenance costs in an item as widely used as the watt-hour meter is significant in the operations of electric utilities. The long life inherent through the use of magnetic suspension of the watt-hour meter rotor promises to reduce bearing maintenance to a new low level.

Early Magnetic Suspensions

One of the earliest attempts at magnetic suspension was the ingenious construction used by Stanley in his magnetic flotation meter about 1903. Other proposed constructions during the last half century have resulted in several patents. In some cases magnetic attraction was used only to reduce the weight on the jewels but not entirely to eliminate it. In others, as in the case of the Stanley meter, a reluctance design was used to give complete support. Unfortunately, the earlier designers were limited by the lack of suitable permanent magnet materials making it necessary to use soft iron poles in conjunction with large permanent magnets to obtain the required lifting force. As a consequence, lifting forces were accompanied by potentially large side thrust forces due to flux crowding with any eccentricity or lack of symmetry. Resulting wear on guide bearings caused failure of the system.

Repulsion-Type Magnetic Suspension

In the early 1930's age-hardening permanent magnet alloys, since called the "alnico" group, became available. These alloys had much greater coercivity than had been available, thus making it possible to support a movable magnet by repulsion without the excessive mutual demagnetization which occurs with the

Figure 1. Pivot-type mechanical bearing

Figure 2. Ball-type mechanical bearing

materials of lower coercivity. The possibility of applying this repulsion property to supporting the meter rotor was recognized and samples were constructed. Figure 4 shows the relative arrangement of the lower or fixed magnet and the upper magnet which was attached to the rotor. This arrangement showed much promise since stable vertical equilibrium was established and side thrust forces were not excessive with reasonable radial displacement of the upper magnet with respect to the lower magnet. Later the aolly "cunico" (Figure 5) became available.[6] This represented a great advance because the material not only had high-coercive properties but it also was machinable whereas "alnico" could only be cast, sintered, or ground to shape. During the course of applying the "cunico" material to the repulsion-type suspension, a concentric arrangement of magnets was conceived. This offered so many advantages that all efforts were placed on it, resulting eventually in a practical solution of the long desire to support the watt-hour meter rotor magnetically.

Concentric-Type Magnetic Suspension

Figure 6 shows the arrangement and direction of magnetization of the "cunico" stator and rotor magnets of the concentric suspension as well as the associated flux distribution. Here, as in the repulsion system, the components are cylindrical so that the fields can be visualized in three dimensions, as a rotation of the 2-dimensional plots about the axis *YY*. The repulsion system (Figure 4) yields a large amount of leakage flux (*L*) which does not contribute to the lifting force, as only the flux immediately adjacent to *N-N* is effective.

In the concentric system, most of the flux is of value, and only a small percentage of leakage flux must be tolerated. Moreover, vertical force is provided at both ends of the concentric magnets by attraction between north and south poles.

Although both repulsion and concentric arrangements can be developed into practical systems, the decision to concentrate on the concentric system was made on the basis of the following facts:

1. The concentric suspension can be located at the top of the shaft, where it is remote from disturbing fields due to severe surge conditions in the current coils. In its best mechanical design the repulsion system must be located at the bottom of the shaft.

2. The concentric system results in lower radial or side thrust forces than the repulsion system for any given eccentricity of the rotor.

3. With materials now available, the concentric system is stiffer than the repulsion system.

4. The repulsion system must incorporate a shield to minimize locking torques with the neighboring magnetic materials (the damping magnet or the steel of the electromagnet). The concentric system is self-shielding.

5. For equal lifting force, the rotor magnet of the concentric system is smaller in diameter than the rotor of the repulsion system; thus magnetic locking effects are inherently smaller in this design.

These facts are based upon experience with the most appropriate permanent magnet material available today, namely, "cunico." Possibly, as research discloses new permanent magnet materials, the repulsion system will find application.

In all practical magnetic suspension systems, downward displacement of the moving system produces an upward re-

Figure 5. Demagnetization curve of "cunico"

Figure 7. Vertical load-deflection curve of the concentric-type magnetic suspension

storing force, giving stable equilibrium in the vertical direction. Radial forces are balanced for a perfectly concentric system producing no net resultant. Off-center displacment, however, results in a lateral force tending to increase the eccentricity. Thus, a guide system is essential to maintain equilibrium, and assure concentricity with negligible radial thrust.

The vertical load-deflection curve of the concentric system is shown in Figure 7. At the operating point, which corresponds to the weight of the suspended system of 17.6 grams, the slope is 0.005 of an inch per gram. Experience has proved that this gradient or stiffness is more than adequate to assure a stable vertical position. The curve for radial thrust versus off-center displacement (Figure 8) shows that the concentric system approaches closely the ideal suspension. With an eccentricity of 0.002 of an inch allowed for manufacturing tolerances, the force is less than 0.3 gram.

Mechanical Construction

The concentric suspension as applied to a watt-hour meter rotor is illustrated in Figure 9. The disk and shaft are essentially conventional in construction and similar to other meter designs. The outer "cunico" magnet and upper guide pin are assembled concentrically by means of die cast construction. This assembly is adjustable for height in the meter frame. The inner magnet is attached to the meter shaft also by means of die casting.

Both magnets are machined to close dimensions from "cunico" rod stock. The die casting assembly technique and the close tolerances assure good concentricity. The guide pin in the outer magnet assembly engages the guide bushing of the inner magnet maintaining alignment of the top of the shaft. A similar arrangement is used at the lower end where the guide pin is part of another die-cast assembly adjustable for height. No lubrication is used.

Figure 6. Magnets of concentric-type magnetic suspension showing flux distribution

Co-ordinated Meter Design

The concentric-type magnetic suspension inherently has practically unlimited life because of the extremely small forces on the running surfaces. The new meter in which the magnetic suspension has been incorporated has been designed with coordination to complement the suspension. The principal feature is the location of the braking or control magnets. In the conventional meter, the arrangement has consisted of an assembly of two magnets located at the front of the disk. In the new meter, there are two braking magnets which are cast as inserts in the frame, one on each side of the shaft. Figure 10 illustrates this arrangement, which has important consequences on both the side thrust and vibration forces in the rotor. Side thrust originates in the combination of driving and braking forces which act on the disk. In Figure 11, these forces are indicated for the magnet arrangements of both the conventional and the new meter. In each case the driving torque is produced by a force which may be considered to act on the disk at a point approximately in the middle of the electromagnet at the rear of the disk, Figure 12.

The braking forces act at the location of the braking magnets. In the conventional meter the braking force is in the same direction as the driving force. The moments of these two forces about the shaft are equal and opposite, but the resultant side thrust, which the bearing system must carry, is the sum of the two. In the new meter the braking forces act under the two side-located magnets to produce pure torque. The only side thrust is due to the driving force. At maximum load in the new meter the side thrust is only six grams, with one gram applied to the upper guide pin and five grams on the lower guide pin. Translated into pressure the maximum side thrust corresponds to a pressure of about 100 pounds per square inch. This is in striking contrast to the high pressure in a mechanical bearing, which is present at all loads.

The relocation of the braking magnets and the like polarity with which they are magnetized serve also to reduce vibration. In any meter there are two principal sources of disk vibration. One is due entirely to the potential flux and it takes the form of motion at 120 cycles per second (for 60-cycle supply) in a direction at right angles to the face of the meter. Being caused by potential flux alone it is unchanged in the new meter. The other vibration comes from interaction between the braking magnets and the current set up by the potential flux.

In Figure 13 it is analyzed for both the conventional and the new meter. The forces produced have a frequency of 60 cycles per second, and in the conventional meter they result in an oscillating couple, as the two magnets of the pair are of opposite polarity. This couple produces a lateral motion at the shaft, and in com-

Figure 8. Side thrust due to eccentricity in the concentric-type magnetic suspension

Figure 11. Comparison of side thrust forces due to meter operation

bination with the 120 cycle back-to-front force makes the mode of oscillation of the disk a "figure 8" pattern. With the magnets located at the side and magnetized in the same polarity, the 60-cycle vibration forces in the new meter are almost exactly opposite in direction and produce a negligible resultant.

The vibration patterns produced by these two conditions of operation may be graphically illustrated by a technique in which tiny mercury drops condensed on the blackened surface of the disk are photographed at high magnification.[7] In order to eliminate from the comparison any effects due to the bearing or suspension system itself, the procedure was adopted of suspending the disk assembly without appreciable sidewise restraint. Patterns obtained by this technique are shown in Figure 14. The lesser vibration inherent in the new design is obvious from the figures produced. Like the reduced side thrust, this lesser vibration gives the magnetic suspension more favorable operating conditions. It allows the guide pins to be shorter and stiffer than would otherwise be possible, making a more compact and practical design. At the same time, noise is maintained at an exceedingly low level at all loads and without lubrication.

Figure 9. Cross-section of magnetic suspension in a watt-hour meter

Performance of the Suspension

The ultimate proof of the magnetic suspension to replace the traditional mechanical bearing must come from actual tests in meters. The usual operating characteristics, such as load and voltage curves, frequency, power factor, and temperature curves are not affected in any significant way. The suspension has some influence on starting watts. If the material of the magnets is not perfectly uniform magnetically, or if the magnets are not perfectly concentric with the axis of rotation, a small torque will occur in the suspension, which varies in magnitude and direction around one revolution of the rotor.

By maintaining close dimensional tolerances and rigid inspection of material, this effect is made small, but such torque tends in general to increase starting watts. Acting in large measure to offset this, however, is the improved concentricity of the disk about the axis of rotation. This is possible by the use of the guide bushing in the shaft to replace the pivot or jewel cup of the mechanical bearing. Reduction of disk eccentricity decreases an important item in the components which control starting watts.

It is natural to suppose that short-circuit currents and lightning surges in the meter might produce magnetic fields strong enough to affect the suspension. It is shown by extensive tests, however, that this is not the case. The suspension is located at the top of the shaft, where it is fairly remote from the current coils. Moreover, the magnets, besides being made of the high-coercivity material "cunico," are protected in appreciable measure by being encased in a die-cast housing of conducting material. Following general magnetic practice the magnets are stabilized also by a knock-down field after saturating. No significant weakening of magnets due to time, temperature, or heavy current surges has ever been detected.

Figure 10. New watt-hour meter less cover and register

Life Tests

In order to establish beyond a doubt the permanence of the suspension magnets, life tests have been in progress since 1941 in about 200 meters. They are operated at varying loads on a daily cycle, including light load, rated load, and 400 per cent load. This cycle gives about ten times normal registration, so that in $6^1/_2$ years the registration has totaled the normal registration of 65 years, or about 80,000,000 revolutions. The tests have

Figure 12. Rear view of frame, electromagnet, and disk assembly showing relative positions

Figure 13. Comparison of vibration forces caused by eddy currents due to potential flux reacting with braking magnet flux

shown excellent stability for the magnetic suspension, for in all samples the disk height has been maintained and there apparently is no reason why this will not be so indefinitely.

At the outset it was realized that great care would probably be necessary to detect any effect of time and wear. Accordingly, check points were chosen that would reflect any change in friction, separate and distinct from other factors affecting calibration, such as changes in the effective position of any of the adjustments. The most significant value found was a quantity which has been designated "Δ" (delta), which is obtained by taking both forward and reverse readings at full and light loads. Expressing meter registration in per cent of true watt-hours it is given by

$$\Delta = \frac{\text{F.L. forward} + \text{F.L. reverse}}{2} - \frac{\text{L.L. forward} + \text{L.L. reverse}}{2}$$

Increase in friction at light load will increase this value, whereas other causes of calibration change will not affect it appreciably. An increase in delta will cause a corresponding decrease in light-load registration. To show the response of the life-test meters, changes in delta are plotted as a function of time and the meter registration in millions of revolutions.

The life test was designed as a proving ground for the proper guide-bushing materials, as well as a check on the stability of the magnetic suspension. Nineteen combinations of guide-bushing materials were included in the life test, all without lubrication. Early failure was found in one group. All other groups have maintained operation, and the results on the meters with five of the best material combinations are shown in curve *A* of Figure 15. This grouping includes 57 meters and the average change in delta is plotted. This curve shows the very satisfactory condition of only a small increase up to 0.13 per cent at the start of the test with a subsequent decrease so that at the last two observations, the friction is slightly less than at the start of the test. For comparison, curves *B* and *C* show corresponding data on standard pivot-type bearings and ball-type bearings. In both instances, with some variation during the life test, the general trend has been upward with an increase in delta or friction of 0.25 per cent apparent at the last check.

While the performance of the pivot-type and ball-type bearings is satisfactory and in line with good service experience, it must be recalled that these are accelerated tests and that the factor of time separate and apart from meter registration must have more influence on the pivot and ball-type bearings than on the magnetic suspension guide bearings where there is no question of lubrication and the bearing pressure is much lower. Thus, the superiority of the magnetic suspension apparent in these tests should be confirmed to a greater extent with extension of the test and in service.

With several alternatives in satisfactory bushing materials, choice of the production material could be based not only on the life test results, but also on suitability for manufacturing with the required precision, freedom from corrosion and oxidation for years, continued availability, and control of quality. Considering these factors and excellent experience on the life test, the combination of graphite guide bushings running on stainless-steel guide pins was chosen in preference to other satisfactory combinations which included various laminated plastics in combination with stainless steel. Graphite is very inert, can be machined readily with precision, takes on a smooth gloss without appreciable wear on the contact surface, and should last indefinitely.

Figure 15. Results of life test on magnetic suspensions compared to mechanical bearings

Changes in delta are equivalent to changes in friction

Conclusion

The magnetic suspension described in this paper approaches the ideal for a watt-hour meter bearing system. Mechanical pressure at its highest is of the order of 0.05 of one per cent of that occurring in mechanical bearings. Materials of the guide pin and bushing, the only parts in physical contact, are noncorrodible and operate without lubrication. The magnetic material is highly stable and well protected against demagnetization. Extensive tests confirm the conclusion from theoretical considerations that the magnetic suspension will provide long maintenance-free operation. The principle may well be extended to other applications.

Discussion

F. C. Holtz (Sangamo Electric Company, Springfield, Ill.): The presentation of this paper is both timely and stimulating, and the authors deserve much credit for having achieved a practical meter bearing construction which is a definite advance over the pioneer work of Stanley and others. The availability of new permanent magnet materials has lent considerable encouragement to the practical possibilities of this type of suspension, and it may well be the means for improving the reliability of meter performance over longer periods of time than are now generally accepted. The authors distinguish between two types of meter bearings currently being used, but in the writer's opinion, they do not stress sufficiently the higher degree of performance and reliability which has already been achieved by the ball bearing construction. Field tests initiated in 1940 on several hundred meters having ball bearing construction show that the average change in friction of the lower bearing after eight years of continuous operation under the varying conditions encountered in the field is less than one-tenth of one per cent. It is also to be pointed out that no lubrication of any type was employed in these meters either for the upper or lower bearings. The value of delta used by the authors for expressing meter registration in per cent is slightly misleading in that any variations in its value do not necessarily indicate change in friction. This is especially true considering the magnitude of the observed changes illustrated graphically in Figure 15.

Either positive or negative values may result from changes in the meter structure, the positioning of its adjustments or in the magnetic or electrical properties of the materials used in its construction.

In any event, it should be stressed that the variations in its value from time to time are the most important consideration. The authors imply that under actual service conditions, the factor of time would influence the ball bearing construction more unfavorably than the magnetic suspension. There is nothing in the record of performance of ball-bearing meters which could lead to such a conclusion. In fact, it must be admitted that we do not have, as yet, any appreciable background of experience with magnetic suspensions on which to draw such a conclusion. The superiority of magnetic suspensions is therefore not established, but it is hoped that it may represent a marked contribution to the problem of meter maintenance. It would be interesting if the authors could give figures showing the manner in which the values of delta on individual meters deviated from the mean in any one set of observations.

The magnetic suspension proposed by the authors is particularly susceptible to willful derangement and may become a source of annoyance to the industry. This fact should not be overlooked and some effort should be made to reduce such possibility. The authors illustrate, in Figure 8, the manner in which misalignment of the components of the magnetic suspension influence the side-thrust. Because of the very appreciable radius of action at points where the bearing surfaces are in contact, it would be interesting to know something about how they affect the value of delta and how this value changes with slight inclinations of the meter. It would also be interesting to have information as to the actual value of the friction of such a bearing system at low speeds of rotation, such as are experienced under light load conditions. As pointed out in the references cited, the figure eight loops shown in Figure 14, could be greatly reduced by proper choice of magnet materials and consequent spacing of the poles in the conventional design of damping systems.

A noticeable decrease in side-thrust under heavy load conditions has, however, been achieved in the damping magnet system used by the authors. This should have a tendency to reduce wear under load.

The authors mention bearing pressures of the order of 200,000 pounds per square inch on meter bearing systems. While this is, in general, true for the pivot-type of bearing, it is not true of the ball bearing construction where the pressures are of the order of 70,000 pounds per square inch, which are well within the practical limits of the materials used in their constructions.

Because of the many factors involved, it may well be that a compromise solution of the meter bearing problem may have possibilities. Experimental work on such constructions has been in progress for a number of years and shows excellent results.

A. R. van C. Warrington (General Electric Company, Philadelphia, Pa.): This paper is of interest to all designers of small devices such as relays which require a low friction level. It is of particular interest to relay engineers, because the increasing demands for speed, sensitivity, and accuracy are threatening to exceed the limits of present designs.

In the application of the watt-hour meter magnetic suspension to certain protective or regulating relays, the limiting factor would probably be the effect of the side-thrusts which increase at higher torque levels. It is at low torques, particularly near pick-up, that the principal benefits of the magnetic suspension will be realized.

The authors are to be congratulated on an excellent paper and an important contribution to the art.

H. E. Trekell, L. I. Mendelsohn, and J. H. Wright: The authors appreciate the kind remarks of the discussors and hope that the paper will serve to stimulate thought on other possible applications, as well as on meters and relays, where it is important that friction be maintained at consistently low levels throughout a long lifetime.

The authors would like a better criterion to measure changes in friction than changes in delta, but, where testing is necessary without removal of parts, no other factor has been found so significant. With a good bearing system, friction values are so small that detection of changes can be readily obscured by other causes of calibration change. On the other hand, it has been the authors' experience that these changes other than friction either are so small as to be negligible, or act in a way not to affect the value of delta.

It is the authors' belief that the magnetic suspension, properly applied, constitutes no significance as regards willful derangement. Possibly the concern in this respect was that it might be possible to demagnetize the suspension causing the disk to drop and drag on the air gap surfaces. This possibility has been eliminated in the construction used. At the bottom end of the shaft, and above the lower guide bushing, a polished end stone of sapphire has been placed. The lower guide pin is located in assembly with only a small clearance between the hardened stainless-steel pin and the jewel. In the event the suspension is demagnetized willfully, the jewel and the rounded and polished pin act as an excellent inverted pivot-type bearing, permitting the meter to continue to operate satisfactorily for many years. With little to be gained there should be little desire to demagnetize the suspension magnets.

Tests, where the meter assembly is tilted off the vertical, show that the magnetic suspension is superior to mechanical bearings because of the better alignment inherent with the guide pins.

Calculations of the stress in new mechanical bearings, using methods in use for years and cited in the authors' references, show the value for pivot-type bearings to be in excess of 200,000 pounds per square inch. The value for ball-type bearings ranges from 182,000 to 199,000 pounds per square inch depending on the weight of the single-phase meter rotor being considered. These values are calculated at zero load on the meter. The addition of side-thrust with increase in load increases the stress.

Effects of Silicone Vapor on Brush Wear

J. MARSDEN
NONMEMBER AIEE

ROBERT H. SAVAGE
NONMEMBER AIEE

THE lubrication of graphite by water vapor is now well known. Many other condensable vapors, however, have been found equally effective and substitute adequately for water. Striking demonstrations of this occurred during the high-altitude testing of aircraft brushes during the war. It was found that certain solvents from the freshly-painted interiors of cold chambers provided vapor lubrication for brushes operating under dry conditions, and brush dusting, which normally would have occurred, was prevented. The easily condensable vapors, as a class, excepting corrosive substances, thus gradually became recognized as lubricants for carbon brushes.

It was extraordinary, in view of this, to find in 1945 that the wear rates of carbon brushes were accelerated by a factor of ten or more when operated in totally enclosed motors having silicone insulation. The high wear could be lowered quickly simply by opening the machine to the normal atmosphere. Silicone-insulated motors which were not totally enclosed showed no such trouble. Initially, it was suggested that silicone vapor from the insulation formed water-repellent films on the commutator and interfered with the action of the water, but this explanation seemed improbable because the normal vapor lubricants for carbon do include water-repellent substances[1] for example, benzene and *n*-hexane.

Thus, some quite different mechanism had to be found to account for the unusual brush wear. This was the status of the problem when it was referred to this laboratory in November 1945.

Initial Apparatus

A few exploratory trials of carbon brushes operating in air under a bell jar quickly proved that the vapors distilled from typical silicone varnishes increase the wear rate by several fold. Special devices were then constructed to study the problem in detail. The initial apparatus consisted of a copper ring (23 millimeters in diameter), mounted on the shaft of a d-c motor (4,000 to 8,000 rpm) and carrying two electrographitized carbon brushes. The entire assembly was enclosed under a bell jar. The brushes were 6.2 millimeter square cross-section and were mounted under spring forces (300 to 400 grams) in radial box-type holders which were fastened to a water-cooled copper plate. Electric connections were made with tapered silver plugs, pressed into holes drilled in the brush sides, and soldered at the outer ends to copper pigtails which were connected to the voltage source. See Figure 1.

Initial Experiments: Effect of Methyl Silicones

With this apparatus, the effects of pure, volatile silicone compounds on brush wear were studied in detail. A typical substance, hexamethyldisiloxane,* was placed under the bell jar in a small beaker near the collector-ring and was found to increase the wear rate for current-carrying carbon brushes on copper from a normal 0.2 mil per hour to about 5 mils per hour. The accelerated wear occurred repeatedly in the presence of this vapor and also in the presence of other methyl silicone vapors (of both the straight chain and the cyclic types) providing the apparatus was enclosed with the vapor source or the atmosphere containing the vapor was recirculated over the brushes. Using individually a series of pure methyl silicone liquids of increasing vapor pressure, a measurable effect on the brush performance (contact voltage drop rise) was noted when the vapor pressure of the source was only 0.007 millimeter (mercury). The typical accelerated wear was obtained when this vapor pressure reached or exceeded about 0.2 millimeter.

This accelerated wear occurred only when the brushes carried current, approaching maximum intensity in the current range 10 to 20 amperes, a fact which is especially significant, as will be seen later. Furthermore, this wear was unlike that noted with brushes in high-altitude atmospheres where the wear-rate is steady and high. In the silicone-accelerated wear, the brushes passed through the following cycles:

1. There is an initial period of increasing voltage-drop frequently attended by sparking but with only slight wear.
2. There is a sudden fall in this drop simultaneous with a large increase in friction during which a cloud of black carbon wear-dust was blown from the brush faces.

This cycle repeated aperiodically as shown in Figure 2. This general effect was qualitatively reproducible, although the wear rates were not, the latter showing variations amounting to nearly one order of magnitude.

Another curious characteristic of the silicone-accelerated wear was a persistent "after effect" upon the brush performance following removal of the silicone

Paper 48-211, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted March 1, 1948; made available for printing July 26, 1948.

J. MARSDEN and ROBERT H. SAVAGE are both with the research laboratory of the General Electric Company, Schenectady, N. Y.

The writers are glad to express their appreciation for many helpful suggestions which have been made in the course of this work by their colleagues, especially those of C. Van Brunt, A. L. Marshall, and F. J. Norton. Thanks are due Charles Foster who carried out a large part of the experimental work with the resins and with the impregnated brushes.

* Vapor pressure = 40 millimeters (mercury) at room temperature.

Figure 1 (left). Brush apparatus

Figure 2 (above). Brush voltage drop in methyl silicone vapor+air

source. This is illustrated by the following typical experiment.

After a run in silicone, the apparatus was opened and was aired for 65 hours. The carbon dust was removed by a compressed-air blast, and the brushes were then operated again with the bell jar still off (ordinary air atmosphere). For about ten minutes the operation was normal. Then suddenly the friction became high, and a cloud of wear dust was thrown from the slip ring, the brushes hissing as though rubbing against an abrasive. This occurred several times before the brush operation was again entirely normal.

The Wear Debris: Origin of the High Wear

The wear dust collected from intermittent dusting periods was examined after several individual experiments. These samples showed, in addition to the large quantity of carbon dust, some copper fragments evidently gouged from the ring. A few of these were several millimeters long, although microscopically thin, indicating that microscopic tools were producing severe abrasion in the contact zone. In addition to the copper fragments, there were found masses of minute thin white plates, some glassy and all closely associated with graphite. These white masses under the microscope were found to be infusible at temperatures up to 1,000 degrees centigrade and were indicated to be siliceous residues. The brush faces from the silicone experiments were found to show white particles concentrated in the zones of real contact (where specular polish had developed), as shown in the photomicrograph, Figure 3. These particles were not revealed until after the gloss had been removed from the brush face by gentle etching.

These, and other observations to be described later, suggested that silicone vapor is oxidized in the zone of interfacial brush contact to form siliceous residues which are apparently the primary cause of the high wear. The insulating films so formed can presumably be removed only by actual wear, their vapor pressures being negligible at the interfacial temperatures. Microanalyses of representative films formed on copper slip-rings and commutators, by carbon brushes operating in air containing silicone vapor, have shown excessive amounts of silica, which is simply the ash resulting from the oxidation of the vapor in the high temperature[3] of the sliding electrical contact.

Silicone Vapor as a Lubricant for Carbon Brushes

When brushes were operated upon a copper disk in vacuum equipment[1] with oxygen excluded, it was found that a silicone vapor (hexamethyldisiloxane), at a pressure of 4 millimeters (mercury), actually provided lubrication as does water in the normal case. No accelerated wear was noted, even under current density of 54 amperes per square centimeter. The voltage drop of the brushes was low and steady in these trials with silicone vapor only. When small amounts of oxygen were introduced, voltage drop showed an unstable rise; and subsequently, with higher oxygen pressure, high friction developed. Experiments of this kind showed that the silicone vapors are stable and actually lubricate graphite in absence of oxygen. When the brushes were operated in a nitrogen atmosphere (in an improved apparatus described in the following pages), it was found, consistent with this, that the silicone vapor again provided lubrication for the brushes.

Sorption of Silicone by the Apparatus

By accident, it was found that certain of the silicone vapors were sorbed in glass apparatus with a persistency similar to that shown by water. For example, following exposure to silicone vapor the apparatus was evacuated intermittently

Table I

Effect of Current[3] on Carbon Brush Wear in Air Atmospheres Containing the Silicone Vapor *$[(CH_3)_2SiO]_3$

Silicone Partial Pressure, mm Hg	Brush Current, Amperes	Wear Rate, Mils Per Hour
0.0	15	0.08
0.3	0	0.08
0.3	3	0.3
0.3	6	0.2
0.3	15	8.7

* $[(CH_3)_2SiO]_3$: Vapor pressure 0.3 millimeter at room temperature. The vapor pressure data for the silicones used in this work were taken from an unpublished report by D. Wilcock dated Aug. 26, 1946.

Table II

Effect of Silicone Vapor on Brush Wear in Various Atmospheres[3]

Experiment	Time of Run, Hours	Atmosphere: Gas	Atmosphere: Silicone Vapor	Wear Rate, Miles/Hour
A	3	$Air+H_2O$	none	0.1
B	4	N_2+H_2O	$[(CH_3)_2SiO]_4$	0.08
C	3	N_2+H_2O	$[(CH_3)_2Si]_2O$	0.1
D	7.8	N_2	$[(CH_3)_2Si]_2O$	0.12
E	3.25	N_2	$[(CH_3)_2Si]_2O$	0.12
F		$Air+H_2O$	$[(CH_3)_2SiO]_3$	8.72
G	15	$Air+H_2O$	$[(CH_3)_2Si]_2O$	13.4

for a period of several days to a pressure below 0.01 micron. Even after this prolonged exhaust, the glass continued to evolve the silicone when the pumps were shut off. Starting at a pressure rise of about 0.5 micron within the first few minutes, the pressure would continue to increase to as much as ten microns silicone vapor in the course of a few hours. This provided a serious source of contamination for brush experiments because of the cumulatively contaminating effects of silicone vapor on brush wear. To avoid this trouble completely, it was necessary to bake out parts of the apparatus.

Some Difficulties with the Initial Apparatus

Although the slip-ring apparatus shown in Figure 1 was useful in providing the foregoing preliminary information, it was not possible to reproduce actual wear-rates in silicone experiments with it, but only qualitative effects. After considerable work, it was decided that this lack of reproducibility was due, at least partially, to a nonequilibrium condition of the silicone vapor in the brush enclosure and to unusual variations in the brush currents.

The latter variations resulted from the abnormally large changes in brush contact resistance which were imposed in a low-voltage circuit. These were the unexpected results of drastic and irreversible contamination of the contact surfaces by the silicone. (It was found in this connection that the voltage fluctuations constituted the most sensitive indication of the presence of silicone vapor in the system, as will appear later, and always preceded the period of incipient wear). The variations in the brush current were easily overcome by connecting the brushes into a higher voltage power-potentiometer, but the variations in the vapor pressure made necessary the building of new apparatus.

Controlled Vapor-Pressure Experiments

The improved apparatus designed by one of us (Marsden) consisted of two parts:

1. There was a train of bubblers through which a carrier gas was passed to supply a known concentration of silicone to the brush enclosure.

2. The other part was a compact enclosure containing the brush and slip-ring device.

The train consisted of an all glass system having, in series, a compressed air or nitrogen source, flow-meter, three bubblers containing a pure liquid polysiloxane (silicone) compound of known vapor pressure, and finally three bubblers containing a saturated water solution of $MgCl_2$.* This led directly to the brush enclosure. The brush assembly was similar to the apparatus initially used, except that a larger motor (1/4 horsepower 4,150 rpm direct current) was substituted, and this was separated from the brush atmosphere by a brass plate fitted with a felt gasket around the motor shaft. Instead of the large bell jar, a small soapstone cylinder was mounted on the plate and was covered with a glass window. This chamber was fitted with neoprene gaskets and was maintained at a pressure equivalent to about 2 millimeters (mercury) above atmospheric.

With this new apparatus, and using a silicone liquid of somewhat lower vapor pressure to moderate the accelerated wear, it was possible to repeat experiment with reasonable consistency.

The general effect of current on the brush wear in this apparatus is shown in Table I. The large increase in the wear rate obtained at the high currents may be understood as the result of increased oxidation of silicone in the contact zone with a greater attendant rate of production of abrasive products.

The explanation of the primary cause of the wear, which has been given is clearly supported by the foregoing results, and also by a separate series of experiments in which nitrogen, purified over hot copper, was substituted for air and passed into the chamber with the silicone vapor. See Table II. These results show that brushes may be operated at a normal (that is, negligible) wear-rate in the presence of silicone vapor if oxygen is excluded. Water vapor apparently does not affect the lubrication in this case.

* 30 per cent relative humidity at 30 degrees centigrade. The humidity was carefully controlled to insure uniformity of atmospheric conditions. However the water vapor concentration within the normal range of atmospheric variation was not found to have an important effect on the silicone-accelerated wear.

Figure 3. Photomicrograph of brush face, showing white masses in the contact zone, after etching

Phenyl Silicones

After concluding the experiments with methyl polysiloxane liquids, several attempts were made to obtain comparative data substituting pure phenyl silicones. Because the vapor pressures of the phenyl compounds are extremely low at the apparatus temperature, it was not possible to pass the vapor into the enclosure without rapid condensation and the attendant uncertainty of the effective concentration of the vapor in the brush ambient. Experiments should be made along these lines with the apparatus heated to prevent condensation. The writers have not found the opportunity to do this. However, a number of trials have been made using brushes impregnated with phenyl silicones and with methyl silicones, respectively, for comparison purposes. After considerable work, it is concluded that this is probably not a reliable method of evaluating a silicone effect, although high wear has been produced by some of the silicones by this means. A few interesting facts however should be noted.

The wear rates (1 mil per hour) of some methyl silicone impregnated brushes containing 4.8 per cent impregnant were especially significant when compared with those (8 mils per hour) of brushes in a methyl silicone vapor, $[(CH_3)_2SiO]_3$, particularly in view of the fact that unimpregnated brushes of the type used were found to sorb only 0.2 per cent by weight even after 18 hours in this vapor at room temperature. These results show that the total amount of silicone sorbed by the brush is not an important factor. What is fundamentally important is the rate at which vapor molecules impinge upon the surface of the commutator and at the brush face.* These molecules have a short adsorption life, of the order of

* Using kinetic theory formulae, the calculated weight of a silicone $[(CH_3)_2SiO]_4$ impinging on unit surface in unit time is 0.02 gram per square centimeter per second.

micro seconds,[4] but this time is seemingly sufficient to allow fixation and oxidation of the sorbed silicone to take place.

Effect of Vapor from Silicone Resins Upon Brush Wear

Summarizing the foregoing experiments, it was indicated that pure, volatile, silicone vapors of low molecular weight increase the wear-rate of current-carrying brushes operating in air by forming abrasive siliceous products. This undoubtedly is the key to the origin of the high wear shown by brushes on actual machines, totally enclosed, where the source of the vapor is the hot insulation. There we may expect products (from thermal cracking) similar to the pure compounds which have been shown to initiate the high wear under a bell jar. In order to throw more light on this possibility, and to apply the principles derived from the studies with pure compounds to actual resin applications, a parallel study was made of brush wear in the presence of hot insulation.

A preliminary study using a hot, organic insulation-varnish showed that the vapors from this material tended, if anything, to decrease brush wear-rates. The subsequent work was therefore confined to the silicone resins, having the reverse effect.

The apparatus was similar to that described under "Initial Experiments" except for minor changes which permitted the continuous passage of air over the brush system from auxiliary equipment outside.

The vapor from the hot insulating resins was passed to the brushes by the following procedure. A controlled air stream (160 cubic centimeters per minute) was passed through a series of four saturated magnesium chloride bubblers, then through a glass tube which contained the strips of resin-coated glass tape* and which was enclosed in a muffle furnace, and finally, through heated glass tubing directly to the brush track. This was intended to duplicate qualitatively the totally enclosed motor set-up in which the cooling blast, for the commutator, streams across the hot armature, carrying along the volatile components from the windings of the machine to the brush ambient.

With this equipment a long series of experiments was made[3] having the objects of determining the effect of the "resinous vapor" upon the wear, and of finding whether the accelerated wear could be prevented by a more complete curing of the resin. For this purpose the brushes were tested in the vapor evolved by standard-cured resins which had been obtained from each of two manufacturers of silicone insulation, and in the vapor from supercured resins, baked at temperatures in excess of those required to effect a normal cure.

The data showed that all of the resins, when heated above 175 to 200 degrees centigrade, increased the wear rates of the brushes. They showed also that the brush wear, caused by the vapor which was evolved by heating a typical resin at 250 degrees centigrade, was reduced by prior supercuring of the resin, effected by heating at 250 degrees centigrade for 16.5 hours. After additional supercuring at 250 degrees centigrade for a total of 52.5 hours, no additional reduction in brush wear was noted, and at the end of this time the brush wear was still four to eight times greater than normal wear. The silicone-coated resin tape continued to lose weight, and in the latter stage of heating there was no change in the slope of the weight loss curve. This general effect was found for all of the resins which were studied and may be regarded as especially significant in view of the fact that the supercuring was sufficient in some instances to reduce the useful insulating life of the resin by an estimated 65 per cent.

Weight loss data for the resins which were heated at 250 degrees centigrade for a rather long time (56 hours) were taken. The data showed that the slopes of the weight-loss curves, both in air and in a nonoxidizing atmosphere (nitrogen), were nearly identical. This fact indicated that little oxidation occurred when the resin was heated in air. On the basis that oxidation of two methyl groups leads to the formation of an oxygen bridge, the weight loss data indicate that less than 2 methyl groups per 100 silicone atoms are oxidized.

It is suggested from this work that the continuing weight loss, even after heating for a long time at 250 degrees centigrade, is due not to the removal of volatile material originally present in the resin after preparation, but rather due to the removal of volatile fragments produced by thermal decomposition of nonvolatile polymer. This result is particularly important because it indicates that accelerated brush wear will persist until the useful insulating life has been largely destroyed.

Solutions for the Problem

We are thus led to a consideration of means to overcome the accelerated wear other than by the supercuring of the resin (although that is a partial aid). The experiments of one of us (Marsden) showed that brushes, which had been impregnated with certain lubricant liquids, could be operated in air atmospheres containing silicone vapor for extended periods without showing accelerated wear. In these experiments it was found that, under heavy current loading, these brushes gradually lost their impregnant by evaporation as a result of which the wear-rates gradually became excessive. It is suggested that with more research along these lines a longer term solution to the problem might be obtained.

However, a quite different approach to the problem is already under engineering development; namely, the isolation of the brush system from the atmosphere containing the traces of silicone vapor, by enclosing the commutator and brushes in a separately pressurized compartment so that the vapors cannot reach the brush zone of rubbing contact. This procedure appears to provide a practicable and effective solution to the problem.

It is to be noted that the high wear produced by silicone vapors in air atmosphere has not been found to occur on machines which are ventilated, so that apparently no problem openly exists for most motor applications of these high temperature insulations.

Conclusion

1. In the presence of oxygen, and in a confined space, methyl polysiloxane (silicone) vapors are found to accelerate the wear of current-carrying carbon brushes several-fold (and up to 800-fold under the severe conditions of high silicone concentration coupled with high-current density).

2. This high wear occurs as a series of intermittent dusting periods, each lasting for only a few seconds, and each preceded by excessive build-up in the contact voltage drop, due to an irreversible contamination of the rubbing interface by silicone decomposition products. The momentary dusting period cleans off the insulating layer and exposes fresh surface for a repetition of the buildup and dusting cycle.

3. It appears that the most important step causing the wear is the oxidation of silicone to silica, or to a siliceous residue, which occurs in the zone of interfacial rubbing contact.

4. In the absence of oxygen, silicone vapor is stable and actually lubricates the graphite at a pressure of a few millimeters (mercury). This occurs independently of the presence or absence of water vapor.

5. Brushes impregnated with silicones

* 25 to 30 strips (12.5 centimeters long) were stacked loosely in a weighed glass tube parallel to its axis. The resin had been cured by standard procedure and was representative of that which is used on commercial totally enclosed d-c motors. The weight of resin was estimated from the weights of equal lengths of bare glass tape and resin-coated tape, and corresponded to about ten grams per charge.

(liquids or solids) may show the accelerated wear when run in ordinary air, but their use does not provide a reliable criterion of the wear that occurs when nonimpregnated brushes are operated in air containing silicone vapor.

6. The vapors, produced by heating, of each of the silicone resins investigated caused excessive brush wear. These resins included the principal commercial types currently available.

7. Long-term curing of these resins does not eliminate entirely the loss of volatile material, and so does not eliminate entirely the excessive brush wear which occurs when these resins are heated at high temperatures within the brush ambient.

8. It is shown that brushes impregnated with certain organic liquids (not silicones) do not wear at an excessive rate in silicone vapor until most of the impregnant has been evaporated from the brush as a result of high-temperature operation. It is suggested that further work with impregnated brushes might yield a longer term solution to the wear problem.

9. The most practical solution appears to be the isolation of the brush system from the silicone vapor evolved from the machine windings by means of a separate pressurized compartment in the totally enclosed unit.

10. No accelerated wear problem has been reported to exist in silicone-insulated machines which are not totally enclosed, so that the solutions outlined under (8) and (9) need be applicable only to the relatively small but important number of machines in which vapors from hot insulations are recirculated within the brush ambient.

No Discussion

The True Dielectric Breakdown Strength of Electric-Cable Insulating Papers

PAUL CLOKE
FELLOW AIEE

BURT BATES
NONMEMBER AIEE

THE dielectric breakdown of electric-cable insulating papers has been the subject of intensive study over a period of many years. One of the major difficulties has been the elimination of the edge effect.

In the case of glass, this was accomplished by blowing thin glass spheres and testing them between mercury electrodes. This insured that the glass would break down through the thin portion and thus give the true strength of the glass.[1] Use was made also of special semiconducting baths when flat specimens were tested. Moon and Norcross used both of these expedients in testing glass, celluloid, and mica.[2]

Whitehead[3] tested electric-cable insulating papers by spiraling 1-inch papers on a brass tube in much the same manner as is done in electric-cable manufacture. He tested a built-up wall of insulation tapes with oil gaps between turns.

The purpose of this paper is to present a new and unique way of eliminating edge effect and obtaining results which give the true breakdown strength of the paper, with a single voltage wave. Some breakdown strengths obtained by other investigators, with different test conditions, are given for comparison.

Apparatus

The apparatus consisted of a specially shaped electrode and a saturated paper sample, with build-up paper to fit the surface of the special electrode. The equipment for applying the voltage (Figures 1 and 8) consists of a 15-kva 220-to-150,000-volt testing transformer which may be connected on the low-voltage side to a capacitor, which is charged through a kenetron. On the high-voltage side, the terminals are connected through a limiting resistance and inductance to two 0.012-microfarad capacitors in series which, in turn, are in series with a 1-microfarad 1,000-volt capacitor. The three capacitors are paralleled by the sample of paper to be tested. The oscilloscope (persistent screen type —45 seconds) is connected to the 1-microfarad capacitor on the high-voltage side of the transformer.

Method

The capacitor in the low-voltage circuit is charged to a sufficiently high voltage to give a puncture of the paper on the high-voltage side. This capacitor is charged, and then discharged into the low-voltage winding of the transformer. The deflection of the beam on the oscilloscope, at which the paper breaks down, is easily read.

Computations

Since the oscilloscope was calibrated by both a standard direct and an alternating sine-wave voltage (which checked very well), it was possible to compute the total voltage across the sample from the known capacitances of the capacitors in the high-voltage circuit. The capacitances were determined with a standard bridge.

The Special Electrode

The unique feature of this investigation is the specially shaped electrode, the design of which is described subsequently. This entails a new physical structure by which edge effect is eliminated on sheet material, such as paper. Moon and Norcross, and Whitehead used methods which were electrically equivalent to the one used in this investigation. Moon and Norcross[2] used thin glass spheres filled with, and immersed in, mercury, as well as flat specimens in semiconducting baths. Whitehead[3] used test specimens consisting of 16 layers of 5-mil cable paper, one inch wide, spiraled cable-fashion on a smooth brass tube, one inch in diameter, 48 inches long, with 33 1/3 per cent overlap and nominal 3/64 inch channel width.

Empirical Relation

In designing the special electrode which will be described, it was assumed that the dielectric strength of the paper in the transverse direction was approximately 50 times greater than in a longitudinal direction. This was the result of experience in cable testing.

The results showed that between 55.9 and 66.3 per cent of the punctures occurred on the flat, central part of the electrode.

Design of Special Electrode

Referring to Figure 2 (not to scale; see Figure 3), the bottom electrode E is a highly polished, circular, flat disk. The paper sample is represented as P, and the special electrode as S.

The electrode S was made in two sections; the first was perfectly flat for a distance of 1/2-inch radius from the center, and the second half was machined according to the curve derived below.

The basic equation used in the derivation is as follows:

$$\frac{b}{t} = K \qquad (1)$$

Where

Paper 48-212, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted November 5, 1947; made available for printing July 26, 1948.

PAUL CLOKE is dean of the College of Technology, at the University of Maine, Orono, Me. BURT BATES is also of the College of Technology at the same university.

The authors wish to express appreciation to R. W. Atkinson of the General Cable Corporation, Bayonne, N. J., and Roy P. Whitney and David Forrant, both of the University of Maine, for their kind assistance and suggestions. It was Atkinson who suggested the investigation.

Figure 1 (left). Electrical circuit diagram

Figure 5. Specific gravity versus breakdown voltage

b = the angle, in radians, between the tangent to the curved portion of the electrode and the horizontal

t = the thickness of the insulation plus the thickness of the reinforcement, in mils

K = a constant

At the point where the curved portion of the electrode is in contact with the flat portion, the cotangent of b is taken as 50. The value of the derivative at any point on a curve is equal to the tangent of the angle at which a tangent line, drawn through that point, meets the horizontal. Stated mathematically

$$\frac{dy}{dx} = \tan b \qquad (2)$$

If the insulating paper to be tested is approximately 5 mils thick, then

$$t = y + 5 \qquad (3)$$

When cotangent $b = 50$, $b = 0.02$, and $y = 0$. Substituting these values in equations 1 and 3 gives $K = 0.004$.

Combining equations 1, 2, and 3 gives,

$$dx = \frac{dy}{\tan K(y+5)} = dy \cot K(y+5) \qquad (4)$$

The integrating of dx between 0 and x, and $f(y)$ between 0 and y in equation 4 gives

$$x = \frac{1}{K} \ln \sin K(y+5) + C \qquad (5)$$

where

C = constant of integration, and when evaluated, by letting $y = 0$, is found to be 978.

This gives the following equation of the curved portion of the electrode:

$$x = \frac{1}{K} \ln \sin K(y+5) + 978 \qquad (6)$$

Figure 3 shows the actual dimensions of the curved portions of the special electrode. The formula derived is that which is required to keep the tangential stress below the known tangential, dielectric strength of the reinforcement in insulation.

Figures 2 and 4 are enlarged to clarify the design features. They are not to scale.

Build-Up Paper

The build-up paper should be of very thin rice paper, or preferably, of the same kind of paper as the sample to be tested, and sandpapered down to fit the curved portion of the special (upper) electrode.

The function of the build-up paper is to confine the puncture to the central, flat portion of the special electrode, and thus puncture the paper samples. The build-up paper and special electrode are the really unique features of the investigation. Even if edge effect were entirely eliminated, some breakdowns would undoubtedly occur outside the central area because of variation in the paper. For the majority of tests, the build-up sheets were made of 1-mil paper. The build-up sheets were cut with an outside diameter of three inches and with varying sizes of circular holes in the center. The diameters of the holes in inches are as follows: sheet 1, 1.000; sheet 2, 1.080; sheet 3, 1.162; sheet 4, 1.232; sheet 5, 1.288; sheet 6, 1.344. The total build-up paper was made by gluing sheet 2 on sheet 1, sheet 3 on sheet 2, and so on, by means of a small drop of glue on the outer edge of the sheets, where the glue would not come in contact with the electrode. When the total build-up paper was made, the shape of the electrode was approximated by the depression formed by the holes in the center of the build-up paper.

In some cases, sheet 1 was omitted. For some tests, the insulating-paper samples were used as build-up paper by cutting a 1-inch, or a $1^1/_8$-inch hole in the center of the paper, and tapering the center circle by use of fine sandpaper. Another variation was the use of half mil paper for build-up. In this case, 11 sheets were used for the build-up paper. The inside diameters in inches for these sheets are as follows: sheet 1, 1.000; sheet 2, 1.040; sheet 3, 1.880; sheet 4, 1.121; sheet 5, 1.162; sheet 6, 1.197; sheet 7, 1.232; sheet 8, 1.260; sheet 9, 1.288; sheet 10, 1.316; sheet 11, 1.344.

In all cases, enough sheets were used to give a total thickness of build-up paper of at least five mils. All paper samples,

including the build-up papers, were dried for 24 hours at 105 degrees centigrade and one millimeter (mercury) of pressure. The samples were then impregnated with transformer oil at 105 degrees centigrade.

Breakdown Test

All samples were tested under oil in an earthen crock. The oil was continually filtered by a circulating pump. The crock was kept well covered, when not in use, so that very little dirt could get in the oil.

The breakdown tests were short in duration, but a great amount of care was necessary to measure the breakdown voltage accurately. The oscilloscope was connected across capacitors in the voltage divider circuit of such a value that the deflection on the oscilloscope would fill the screen. The capacitance was kept constant at 1.03 microfarads during the investigation.

Build-up paper was placed on the sample and carefully centered. The combination was placed on the electrode, and the top electrode adjusted so that its curvature was in the build-up paper. This was one of the most difficult parts of the test to perform accurately. The electrode holder was then lowered into the crock.

When the paper sample was adjusted properly, the capacitors in the low-voltage transformer circuit were charged by the variable d-c power supply, to a potential high enough to cause breakdown.

After all preliminary adjustments were made, the capacitors were discharged through the low-voltage winding of the transformer. This caused a high voltage in the high-voltage winding, breaking the paper. The following data were recorded for every run: the direct voltage to which the capacitors, connected to the low-voltage winding of the low transformer, were charged; the position of breakdown; the vertical deflection of the beam on the oscilloscope; and the value of capacitance across the oscilloscope.

Figure 5 shows the relation between breakdown in volts per mil and paper density. Specification of polarity is not essential since the stresses at the two electrodes are essentially the same.

Table II

Samples	Breakdown, Kilovolts Per Centimeter	Volts Per Mil
Glass	4,500	11,400
Celluloid	2,500	2,500
Mica	10,600	26,900

Distribution

A study of the distribution of breakdowns over the face of the one-inch, central portion of the special electrode shows that the actual distribution checks quite well with the theoretical, computed distribution on the basis of annular, concentric zones of equal area.

Figure 6 shows the wave form of the puncture voltage. The timing wave is 600 cycles.

As a result of the tabulation and comparison of data obtained in this investigation, the following conclusions were reached:

1. The special electrode and build-up paper made possible the determination of the breakdown strength under surge voltage for single thicknesses of oil-impregnated paper.

2. The build-up paper is necessary, and the best results were obtained when build-up paper was made from the sample paper.

3. The breakdown voltage obtained in this investigation is about twice as great as that found by other investigators.

4. The range of breakdown voltage was quite wide, but seemed reasonable for dielectric strength tests.

5. The actual percentage of breakdowns which occurred within the central 1-inch portion was fairly close to the theoretical value. This is on the basis of concentric zones of equal area on the central portion of the special electrode. Rather a high percentage of breakdowns, however, occurred outside of this area, as would be expected statistically. As has already been pointed out, breakdowns would occur outside the one inch center, even if edge effect were entirely eliminated.

6. The breakdown voltage increases with increase of specific gravity. Data, obtained in our tests, are seen in Table I.

Some Comparisons

Moon and Norcross[3] obtained the results shown in Table II in the disruptive region, with applied direct current, using mercury electrodes for thin glass or semiconducting baths for celluloid and mica.

Whitehead and Kopper[2] found the values for insulating papers, as shown in Table III.

In comparing these tests with data published previously concerning paper or

build-up-paper insulation, it must be recognized that the quantities measured are not the same. These tests have developed the specific or inherent (short time) strength of the saturated paper. Tests on sheets or tapes in which the edge effect is not controlled give results that are a function of various things not intrinsic to the paper. Tests on build-up insulation are related to the structure and to the properties of the space between tape edges; specifically, Whitehead shows that the failure in his samples is a function of the stress in the oil between tape edges. Moreover, in comparing the numerical values of these tests with tests at 60 cycles the effect of time must be considered.

One of the most interesting comparisons that can be made is with Whitehead's results. The relative numerical values of his tests and these are essentially a measure of the different voltage schedule and of the fact that, in his type of sample, the test is essentially a measure of the strength of the oil film. It is for that reason that he obtains decreasing strength of the insulation with increasing density of the paper. In the present tests, the fact that the true strength of the paper is developed results in increasing strength with increasing density.

Halperin and Shanklin[4] report 1,330 volts per mil in cables with thicknesses of 125 to 600 mils with a $1^1/_2$–40 wave. They also report 2,400 volts per mil adjacent to the conductor.

One manufacturer names values of 1,200 to 1,800 volts per mil (rms, 60 cycles per second) as minimum average values in material specification for paper. These are based on American Society for Testing Materials (ASTM) specification *D-149*. The electrodes used are square ended, 1/4-inch diameter cylinders. The voltage is increased at the rate of 250 volts each five seconds until failure. The paper is dried and impregnated with oils such as used with solid-type cables, having a viscosity of around 100 seconds at 210 degrees Fahrenheit.

The standard ASTM sheet tester gives breakdown values as high as 2,500 volts per mil (rms 60 cycles per second) on high-density draft paper (specific gravity 0.95). This is equivalent to a peak of 3,500 volts per mil. Since the sample is 5 mils thick and the voltage is raised at the rate of 500 volts per second, the time of voltage application is 25 seconds. For an impulse application of voltage in 0.8 millisecond it would be expected that the

Figure 8. Equipment

Figure 9 (below). Oven and vacuum tank

breakdown value would be 30 per cent or higher. As between the ASTM samples and our tests, there are three fundamental differences. One is our elimination of edge effect; another difference is that one is 60 cycles and the other a short time surge; and the third difference is in the size of the specimen.

As far as the authors are aware, no reports have been made giving surge strengths exceeding 3,000 volts per mil. The difference in our results is likely due either to reasons such as discussed by Whitehead or to edge effect as in ASTM procedure. In Table IV, the total for positions 1, 2, and 3 give the breakdowns occurring on the central 1-inch diameter flat portion of the electrode. Figure 7 shows the sections of the electrode referred to as "position" in Table IV.

60-Cycle Tests

Sixty-cycle tests were considered before the project was started, also ASTM tests. While these results might give added interest to the paper they are not essential in fulfilling the primary purpose of the investigation.

Discussion

C. E. Betzer (Commonwealth Edison Company, Chicago, Ill.): The results of this investigation are astonishing in that they show breakdown strengths of oil-impregnated paper insulation of 4,800 to 5,000 volts per mil. These strengths are for single thicknesses of paper having specific gravities of 0.9 to 1.0, such as those commonly used in cable insulation, and were obtained under voltage surge. They are considerably higher than the strengths reported by other investigators and are ascribed by the authors to the elimination of edge effects in the test cell. However, the extent to which this development is the explanation is not clear because no comparable results of tests with other test cells are given. The results of tests by other investigators given under the heading "Some Comparisons" were all obtained under some different conditions as to type of specimen, thickness of insulation, type of voltage applied, and time to break down.

These high strengths under voltage surge suggest that some improvements in the methods of using impregnated paper insulation might be possible to take advantage of the high inherent strength. At present the limiting value used in design applications for built-up insulation is about 1,200 volts per mil.

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): Data relating to the inherent dielectric strength of impregnated paper, one of the most important high-voltage insulating materials is shown here for perhaps the first time. It has been shown previously (by Whitehead) that, where a series of overlying saturated paper tapes are assembled into an insulating wall, the dielectric strength (under his test conditions) is a function not of the electrical stresses in the tape itself, but of the stresses in the oil-filled valleys between tape edges. Electrical failure in these oil spaces is propagated into the bordering tapes, and final dielectric failure occurs even though the stresses in the tape just prior to the oil breakdown are far lower than the strength of the tape as determined by Cloke by these newly presented data.

It is thus perfectly consistent that, whereas in Whitehead's specimens, the higher the density of the paper, the lower the dielectric strength, in Cloke's specimens, increasing density is accompanied by increasing dielectric strength.

These data form an important contribution to our understanding of the dielectric behavior of paper insulation. Knowledge of the basic properties of the materials with which we deal may be expected to be of importance in the development of high-voltage products.

G. M. L. Sommerman (Northwestern University, Evanston, Ill.): Workers in the field of dielectric breakdown strength will appreciate the painstaking care which Cloke and Bates have exercised both in the preparation of samples, and in the analysis of results in this investigation on single thicknesses of cable-insulating paper. Also, they will recognize the contribution of an evaluated method for reducing the predominance of edge failures in breakdown tests on sheet insulation. Whether or not the factor of sample preparation time will permit the

use of the new method as a quality control test remains a question.

The authors' explanation of the increase of breakdown strength with paper specific gravity in their tests is a reasonable one, but the high values of their reported breakdown strengths (3,700 to 5,500 volts per mil) call for additional discussion. Some relevant results were obtained by the writer in an investigation conducted during the summer of 1948 at the Westinghouse Research Laboratories. Some of the samples tested consisted of paper pressboard 0.125 inch thick, 0.95 specific gravity impregnated with Wemco C transformer oil. The electrodes were similar in area to those of Cloke and Bates, but the edge effect was practically eliminated by different methods. The average breakdown strength of seven such samples was 2,100 volts per mil with standard $1^1/_2 \times 40$ microsecond surge voltages. This agrees closely with the maximum surge-voltage strength of 2,400 volts per mil obtained by Halperin and Shanklin[1] and is less than half the value of 4,750 volts per mil shown in Figure 5 of the paper under discussion. It should be emphasized that no paper-free gaps existed in these samples, the only practical differences in the two sets of tests being those of sample thickness and of surge-voltage duration. The latter difference cannot account for the discrepancy, because the longer surge duration employed by Cloke and Bates would reduce rather than raise the breakdown voltage compared with standard surge results.

This leaves only (1) the factor of sample thickness, or (2) the possibility of an error in voltage measurement to account for the discrepancy. With respect to (1) it is, of course, well known that measured breakdown strength decreases as sample thickness increases, but the functional relationship is not very steep for surge strengths of high-quality insulation. In this regard it would be of value if the authors could extend their investigation to cover the effect of sample thickness up to the limit determined by their test voltage source. With respect to (2) it would be desirable for the authors to calibrate their capacitance-divider-oscilloscope measuring circuit by means of a sphere gap or a resistance-divider connected to the oscilloscope through the customary cable and impedance-matching termination. Otherwise there is the possibility that surge reflections at the oscilloscope terminals may lead to measured results perhaps twice as great as the correct values.

REFERENCE

1. See reference 4 of the paper.

E. W. Greenfield (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): The authors have presented an interesting study of the dielectric strength of single sheets of impregnated insulating paper.

The idea of building up end re-enforcements by means of specially cut and sanded-to-fit paper sheets glued together is certainly ingenious. However, this proposal would seem to require considerable exercise of skill and a great deal of time so that it probably could not be used for routine testing.

A number of years ago the discusser derived the equation for the slope of re-enforced insulation for cable terminals and

Figure 1. Fiber insulation re-enforcement and electrodes for measuring dielectric strength of sheet insulating materials. Slope designed for a uniform tangential stress of 5 volts per mil

also applied this derivation to the re-enforcement for a paper dielectric strength tester. In this derivation, the solution is based logically upon solving for the tangential stress at the re-enforcement boundary and then forming such a slope which would keep the tangential stress below the known tangential dielectric strength of the re-enforcement insulation. For the cylindrical electrode shape of a cable, this slope turns out to be a log log function. For the parallel plate cell used for paper testing, the slope turns out to be a log-transcendental function and is steeper. Figure 1 of the discussion shows the paper tester with machined permanent re-enforcement made of fiber, into which the shaped upper electrode rests. This type end re-enforcement was found to be moderately successful. No oil immersion bath was required and its use permitted rapid testing.

It is felt that the paper is weak in its comparisons with the work of others. All data should be reduced to a common basis, for example, maximum stress in volts per mil, peak. It would also seem that more emphasis should be placed on the comparisons to be obtained with the standard ASTM test electrodes (1/4-inch flat ended cylinders) rather than with Whitehead's work which was on a cylindrical cable structure, not paper sheet and was a life test.

The standard ASTM sheet tester gives breakdown values as high as 2,500 volts per mil (rms 60 cycles per second) on high density kraft paper (specific gravity 0.95). This is equivalent to a peak of 3,500 volts per mil. Since the sample is 5 mils thick and the voltage is raised at the rate of 500 volts per second, the time of voltage application is 25 seconds. For an impulse application of voltage in 0.8 millisecond it would be expected that the breakdown value would be 30 per cent or more higher. Therefore the question as to what figure represents the "true breakdown voltage" needs to be carefully defined with regard to the conditions of test.

The statement as to the statistical distribution of breakdown is not clearly given in the paper. The tabulated data indicate that most of the breakdowns occurred through the third and fourth layer of the build-up paper. Since the radial stress at this region is only 1/4 to 1/3 the value at the central section, the tendency to fail most frequently through the re-enforcement at this position must be due to tangential stress. Hence "end effects" appear not to be completely eliminated. Also since failures in the re-enforcement are apparently counted in the resultant average, the authors should make it clear that the re-enforcement papers must be of exactly the same material and treatment as for the insulation under test. There will be many who regard failures in the 1-inch diameter single layer area as the only true radial failures achieved by this apparatus.

R. J. Wiseman (The Okonite Company, Passaic, N. J.): Reading of this paper by Cloke and Bates makes one feel that only a part of a research has been made. The test method used seems to be a very good one, particularly the manner in which the shape of the electrostatic field is handled. The desire to get as many breakdowns in the center of the electrodes is quite good and seems to have been accomplished to a high degree. If the authors intended to present a paper describing a method for getting better tests when making dielectric strength tests of impregnated paper, it would seem as if this has been accomplished, provided the sample was tested in an oil medium, as that is the way that the paper is used.

I think the authors should be very careful in making a comparison of the results obtained with results reported by others. Unless the paper is carefully read, one might say that the tests are at variance with others. It must be kept in mind that they are reporting results at probably switching surge frequency, yet they do not say so and I think they should. In fact, I think the correct title to the paper should have been The Dielectric Strength of Impregnated Paper at Switching Surge Frequency. It is not impulse frequency of $1^1/_2/40$ wave nor 60-cycle power frequency. Also they are testing one sheet of paper, whereas actually in a cable we have a multiple number of papers and a gap between turns of each tape. This gap introduces a different dielectric medium which changes the electric stress. This has been pointed out by Whitehead. I wish the authors had made single sheet tests at 60 cycles to prove to us that the higher the density of the paper, the higher the dielectric strength and then take three sheets of paper with a slot about 30 mils wide in the center sheet to simulate the manner in which impregnated paper is used and obtain voltage breakdown figures to prove that that which Whitehead found is correct, namely, that because of the oil in the paper gap and the difference in the specific inductive capacitance of the paper and oil, a lower dielectric strength is obtained as the density of the paper increases.

Let us hope that the authors or someone else will continue this study along the foregoing lines.

Paul Cloke and Burt Bates: Comments by the various people who have discussed the

paper and by the reviewers indicate that 60-cycle tests should have been made. As is clearly stated in the paper, it is hoped that at some future time this may be done. Also some question is raised as to the accuracy of calibrations. Suffice it to say that such a contingency was fully anticipated, and repeated checks and calibrations were made so as to relieve all doubts at least in the minds of the authors. It should be pointed out moreover that in the time available, since the work was done as a graduate thesis, only the tests reported could be made. It is believed that they are of very high accuracy.

Another discusser states that unless the paper is carefully read, the wrong impression might be created. The reply to this is obvious—"Anything worth doing is worth doing well."

In regard to the comment that the authors should be very careful in making comparisons with results of others, let it be stated as was done in the paper, that there is no intention of discrediting any work previously done.

The previous results were put in as is stated so that one might see readily what they were without the necessity of referring to quite a number of other papers. The results obtained under the conditions specified by other investigators are doubtless accurate and true.

Analysis and Redesign of a Carbon Pile Voltage Regulator for Aircraft Generators

W. B. KOUWENHOVEN
FELLOW AIEE

G. J. THALER
ASSOCIATE AIEE

THE carbon pile voltage regulator used on aircraft is an electromechanical device designed to maintain constant generator voltage under the varying loads and speeds encountered. The speed requirement is especially severe as aircraft generators are driven from the main engines and thus are subjected to a speed range of at least two to one.

The basic components of the carbon pile regulator are shown in Figure 1. They are an electromagnet, a spring, and a carbon pile. The electrical circuit of which these are a part is shown in Figure 2. The carbon pile is in series with the generator field and is compressed by the spring unit. The electromagnet is connected across the terminals of the generator and the force that the magnet exerts on its armature opposes the pressure that the spring applies to the carbon pile. Variations in generator output voltage produce changes in the magnet force and thus change the pressure applied to the carbon pile. The regulator is provided with three adjustments: the pile screw; the position of the magnet core; and a rheostat connected in series with the electromagnet. The most important of these is the pile screw which is adjusted, when the regulator is placed in operation, until the proper generator voltage is obtained.

Figure 1. Construction of carbon pile voltage regulator

The principles underlying the operation of the carbon pile regulator are simple; nevertheless, performance has not been altogether satisfactory It was felt that it was desirable to understand thoroughly the basic operation of the regulator itself, and to separate it as far as possible from effects that might arise because of the characteristics of the circuit in which the regulator was used. Therefore, this paper is limited to an analysis of the regulator. Simplified equations are developed for the regulator and are applied both to the analysis of a typical commercial model and to the problem of design. On the basis of this analysis, the regulator was redesigned with a minimum of changes. Two new models were built. These showed greatly improved performance when tested.

The performance characteristics of the commercial regulators are shown in Figure 3, where the variation in generator voltage is plotted against the position of the pile screw, as the latter is turned clockwise, compressing the carbon pile. At first, the voltage rises rapidly from D to C as the pile screw is advanced. At C, a regulator usually becomes unstable, that is, the spring-armature unit begins to vibrate through an appreciable amplitude, producing rapid generator voltage swings. The amplitude may be sufficient to cause the disks in the carbon pile, particularly at the ends, to break contact with each other causing arcs to form between the disks and destruction of the disks. As the pile screw is further advanced, a point B is reached where the vibrations of the spring unit stop and the regulator becomes stable in operation. From B to A, the regulator is stable, and this narrow adjustment range is the region of normal operation. When placing a new regulator in service, the pile screw should be adjusted to provide the minimum voltage in the region B to A. If the pile screw is advanced still further, a rapid rise in voltage beyond A results, because the spring-armature of the magnet is now clamped tightly against the face of the magnet, and further advancement of the pile screw simply serves to compress the carbon pile. The regulator is inoperative, and the generator voltage will build up as in a shunt generator.

A study of Figure 3 shows clearly, that in adjusting the regulator for operation, it passes through a region of instability with the possibility of damage to the disks in the carbon pile, that the operating range is small and the location of the operating point critical. In service, the carbon pile wears, and its length decreases, which is equivalent to backing off the pile screw, that is, moving from A toward B on the voltage characteristics. Eventually, the unit becomes unstable, and the carbon pile rapidly disintegrates, due to arcing, unless a new adjustment of the pile screw is made.

In order to obtain information for an accurate analysis of regulator operation, a number of regulators were studied experimentally. The force versus air gap (armature deflection), for the magnet, and the spring force versus deflection were carefully measured, and also calculated from the known dimensions and characteristics of the regulator. On Figure 4, magnet force versus deflection curves for the average regulator, at sev-

eral values of ampere turns (generator voltage) and, in Figure 5, the force versus deflection characteristics for the springs which are firmly attached to the armature of the magnet are shown.

Force versus resistance and force versus deflection (compression forces) characteristics were measured for a large number of carbon piles, and their average characteristics determined. Typical carbon pile force versus deflection and force versus resistance characteristics are shown in Figure 6. In addition, the air gap, the net force on the carbon pile, and the behavior of the pile in actual operation were measured by special jigs and fixtures designed and built for the work.[3] It was found that in normal stable operation of the regulator, the net force on the carbon pile does not exceed two pounds.

Analysis

For the purpose of this discussion a simplified mathematical analysis of the carbon pile regulator is presented, which serves to explain its operation. In this analysis the characteristics of the external circuit are neglected, and attention is focused on the force equilibrium relations of the mechanical elements of the regulator.

The lack of consideration given to the effects of the external circuit on regulator operation is justified when the regulator operating requirements are considered. The first requirement imposed on any regulator is that it be stable and operate satisfactorily under conditions of constant generator speed and load. The second is that it should re-establish stable performance after a change in load or speed and minimize fluctuations during the transient period. In this second case, the type of external circuit will influence regulator operation and may result in hunting. This does not change the fact, however, that the regulator characteristics should of themselves aid in the restoration of stable operating conditions and that any unbalanced forces set up in a regulator by a transient should tend to produce force equilibrium. It is of interest to note that in none of the tests was there any evidence of hunting.

When the load and speed of the generator are constant, the resultant pressure on the carbon pile and its resistance are also constant if the generator output voltage is to remain fixed. The construction of the regulator is such, Figure 1, that under these conditions, a condition of force equilibrium between magnet, spring, and carbon pile exists as shown by equation 1.

$$F_s = F_m + F_{cp} \tag{1}$$

where

F_s = force exerted by the spring
F_m = force exerted by the magnet pull on its armature
F_{cp} = force exerted by the carbon pile.

Likewise, from the construction of the regulator, a displacement or movement of any one of the component parts (magnet armature, spring or carbon pile) must be duplicated by the others. This relationship is expressed by equation 2.

$$\Delta gm = \Delta ds = \Delta dcp = \Delta x \tag{2}$$

Where

Δgm = incremental change in magnet air gap
Δds = incremental change in spring deflection
Δdcp = incremental change in carbon pile length
Δx = incremental change in displacement (general)

An incremental change or displacement may be caused either by adjusting the pile screw, or by a variation in generator voltage caused by a change in load or speed, or by an external mechanical shock. Regardless of the cause of displacement, equation 1 must be satisfied both before and after the transient period.

Figure 3. Typical performance characteristic of commercial regulators

During the transient period restoring forces should be set up if the regulator is to return to a new stable operating position. This condition is a function of the first derivative of equation 1 with respect to displacement. The value of this differential equation depends upon the particular characteristic of the component parts and three relationships are possible as shown by equation 3.

$$\frac{dF_s}{dx} \lesseqgtr \frac{dF_m}{dx} + \frac{dF_{cp}}{dx} \qquad (3)$$

Case 1. When conditions are such that the rate of change of the spring force with respect to displacement is less than the sum of rates of change of the other two forces with displacement, a set of unbalanced forces exists in the regulator. This condition was found experimentally to result in unstable operation. When these unbalanced forces are present, the magnet will immediately tend either to draw its armature to the pole face or to release it completely. Assume, for example, that the displacement transient is such that the armature is clamped against the pole face. This will cause a lowering of the pressure on the carbon pile and the generator voltage will fall until the spring takes over and drives the armature to its other extreme position. The pressure on the carbon pile will now be a maximum and the generated voltage will build up until the magnet once more asserts itself and draws the armature to the pole face. This will set the spring armature unit into vibration and will result in unstable operation of the regulator.

Case 2. Unbalanced forces also exist in the regulator when the rate of change of the spring force with respect to displacement is greater than the sum of the rates of change of the magnet and carbon pile forces with respect to displacement. In this instance, however, the unbalance apparently is in the form of a restoring force which opposes further displacement, and the regulator is stable as was borne out by the experimental work. For example, assume a transient displacement away from the magnet face, then both magnet and spring forces are decreasing. Under these conditions, however, the rate of change of the spring force with displacement is greater than that of the magnet force, and there exists an excess magnet force tending to restore the spring-armature to its original position. In cases where the transient displacement is in the opposite direction, that is, toward the magnet force, then both magnet and spring forces are increasing, but here the spring force is increasing more rapidly, and it provides the restoring force.

Figure 6. Force versus deflection characteristic of a typical carbon pile

Disk thickness 0.5 millimeter, over-all length 1.5 inches

Case 3. There is a third possible case where equilibrium, as signified by the equal sign of equation 3, may be maintained under all conditions, even transient ones. Under these ideal conditions, no force unbalance with displacement exists and the regulator is stable.

Graphical Analysis

In order to analyse the operating and the adjustment characteristics in terms of the mathematical treatment, it is necessary to make a large scale plot of the individual force deflection characteristics of the magnet, spring and carbon pile. In plotting such a set of curves, displacement or deflection is used as the abscissa and force as the ordinate. The method of locating the origins is as follows: maximum magnet air gap (armature deflection) occurs when the spring is at zero deflection; this displacement is measured and the origins of the two curves are separated by this measured distance. The common ordinate is force, and it is evident from the construction of the regulator that the force exerted by the magnet opposes that of the spring.

The carbon pile force deflection characteristic must now be added to this composite graph. The location of this characteristic will depend upon the adjustment of the pile screw. When the pile screw is advanced, the carbon pile characteristic is displaced from the origin of the spring curve toward that of the magnet curve. The spring characteris-

Figure 5. Typical force versus deflection characteristic of regulator spring

Figure 7 (left). Composite plot of magnet, spring carbon and pile characteristics

Figure 9. Sectional view of regulator with nested cantilever springs

tic, therefore, serves as a reference for the location of the carbon pile characteristics.

Figure 7 shows a sketch of such a large scale plot for the normal operating range (B to A of Figure 3) of a typical regulator. In Figure 7, are a group of magnet force deflection curves (broken lines) for different values of ampere turns (generator voltages) varying from a to e, a spring, and a carbon pile force deflection characteristics. The origin for the carbon pile is located on the spring curve, as described previously. It should be noted that the slope of the spring force deflection, dF_s/dx, is greater than that of the magnet curves for the range shown.

In Figure 7, the operating range of the carbon pile regulator is marked by two vertical lines. The actual location of these limits may be determined either by calculation or by measurement. The line XYZ within this operating range gives a graphical example of the addition indicated in equation 1. The spring force is XZ, the magnet force XY, and that of the carbon pile YZ. The location of the point Y determines the generator voltage corresponding to the given magnet ampere turn characteristic C.

The voltage regulation for the conditions shown in Figure 7 is given by the relation:

$$\text{Per cent regulation} = \frac{\text{Voltage of "a"} - \text{Voltage of "e"}}{\text{Voltage of "a"}} \times 100$$

A composite plot of the actual magnet and spring characteristics of a given regulator is shown in Figure 8. To prevent crowding, the origin of the spring curve is not shown in the figure. The carbon pile curve is also not shown because it could not be separated from the spring curve at the scales used in this plot. This plot may be used to explain the adjustment characteristics of the regulator shown in Figure 3.

Both Figure 3 and Figure 8 are indexed with the letters A, B, C, and D for easy reference. If it is assumed that the operating point starts at D, the voltage is zero, as the carbon pile screw has only been advanced to the point where it just does not make contact with the carbon pile disks. As the pile screw is advanced, the operating point moves along the spring curve from D to C. In this range, the spring curve cuts across magnet characteristics of increasingly greater ampere turn values, and the generator output voltage rises in order to establish the values of F_m required by equation 1. Figure 3 shows that the voltage rises as the pile screw is advanced from D to C. Also, in this region, the slope, dF_s/dx, of the spring force deflection curve is greater than that, dF_m/dx, of the magnet curves. This is a characteristic for stable operation as shown by equation 3 and is confirmed by experiments.

As the pile screw is advanced from C to B, the spring curve recrosses the magnet characteristics, this time from higher to lower values of ampere turns, and the voltage of the generator will decrease. This is confirmed by experiment as shown by Figure 3. It should be noted also that in this range, the slope, dF_s/dx, of the spring curve is less than the slope, dF_m/dx, of the magnet characteristics and that this is a criterion for unstable operation. In the tests, the regulator operation was found to be unstable in this region.

As the pile screw is still further advanced from B to A, the spring and the magnet curves are at first parallel, and then the spring curve begins to cut across magnetic characteristics of higher values of ampere turns. This will result in a range of constant voltage followed by a rise. This is also in line with the experimental results shown in Figure 3. In this region dF_s/dx is either equal or greater than dF_m/dx and the operation of the regulator is stable as proved by experiment.

Figure 8. Composite plot of actual magnet and spring characteristics

Redesign

In view of the experimental and theoretical results, and consideration of production tolerances, it was decided to redesign

Figure 10. Performance characteristic of regulator with nested cantilever spring

Figure 11. Belleville-type spring with cut-away sections

the regulator to satisfy *Case 2*, namely that

$$\frac{dF_s}{dx} > \frac{dF_m}{dx} + \frac{dF_{cp}}{dx}$$

and at the same time to make the spring and magnet force characteristics parallel over as wide a range as possible. Such a design has the advantage that the generator output voltage will be practically constant over the entire pile screw adjustment range and the regulator will be stable in operation.

Before constructing a model regulator to verify the conclusions experimentally, it was decided that the desired conditions could be obtained by redesigning only the spring. Therefore, two different types of springs were designed to match the existing magnet. The first spring was a nested cantilever which approximated a single magnet curve with five straight lines. This spring was not difficult to design, but was bulky, difficult to assemble properly, and extremely sensitive to dimensions and tolerances. The second spring was a Belleville washer type,[8] consisting of two coned disk washers in parallel. The design of this spring is comparatively, very difficult, and an exact match with a magnet curve was not obtained. However, after designing the Belleville spring to give approximately the desired force versus deflection curve, it was found possible to correct the discrepancies by cutting off two pieces from each disk along a chord.

Figure 9 shows a sectional view of the regulator with nested cantilever spring. The five layers pick up at different points throughout the deflection range. Figure 10 shows the regulator adjustment characteristics obtained with the nested cantilever spring. The speeds, 4,200 rpm and 2,400 rpm respectively, are the maximum and minimum rated speeds of the generator used. The curves show nearly constant voltage over a wide range of pile screw position, as predicted, and instability occurs only over a small portion of the adjustment range, and only at maximum speed, no load (broken line section of curve).

Figure 11 shows the Belleville-type spring with cutaway sections indicated. Two such units were used in the regulator, and were operated in parallel with the cuts aligned perpendicular to each other. Figure 12 shows the regulator adjustment characteristics obtained with the Belleville springs. These compare well with the characteristics obtained with the nested cantilever spring, and although not quite as flat, it is thought that the decrease in size and number of parts, as well as the simplicity of assembly and less critical tolerances make it a more practical unit.

In adjusting the regulators, both with the nested cantilever and Belleville springs, it was found that the shape of the regulator adjustment characteristic was appreciably affected by the proper location of the spring armature unit with respect to the magnet face, that is, the air gap for zero spring force. On the graphi-

Figure 12. Performance characteristic of regulator with Belleville-type spring

Figure 13. Sectional view of regulator with Belleville-type spring, illustrating the "link spacing adjustment"

cal representation of the magnet and spring curves (see Figure 7), this corresponds to the displacement between the origins of the magnet and spring curves. It is obvious that this displacement is a critical dimension, since no two magnet curves have exactly the same shape and the spring is designed to match one specific magnet curve. Therefore, it is necessary to be able to adjust the dimension of the mechanical linkage between magnet and spring until the spacing gives the proper displacement between origins. An adjustment was built into the regulator when the Belleville springs were used.

Figure 13 shows a sectional view of the regulator, in which the parts providing the above adjustment have been marked *A*, *B*, and *C*, and called the "link spring adjustment."

In the redesigned regulator, the rheostat in series with the magnet coil is still of value, since this controls the over-all resistance of the magnet circuit, and therefore acts as a voltage adjustment without affecting the shape of the magnet curves. The magnet core adjustment is not necessary.

The effect of adjusting the magnet core is to change the linkage paths in the magnet and therefore the shape of the magnet force versus air gap curves. It is possible that this adjustment could compensate for some variations in spring characteristics, but with well-designed springs the "link spring adjustment" gives better results.

Conclusions

1. The operating characteristics of the present carbon pile voltage regulators have been presented and analysed.

2. A graphical method of predicting performance from the static characteristic curves has been developed with the aid of the mathematics.

3. By application of the methods of analysis it was determined that the present regulators can be improved by changing the spring design. This conclusion is valid for most aircraft applications where hunting due to the external circuit inductance is normally absent. Two regulators with improved springs are described in the paper.

4. In a properly designed regulator the magnet core adjustment is unnecessary, but an added adjustment to control the link spacing was found to result in further improvement in the regulator characteristics.

Discussion

Robert L. Mills and **Donald G. Scorgie** (United States Naval Research Laboratory, Washington, D. C.): The authors have particularly emphasized their chief initial assumption that "the characteristics of the electrical circuit (that is the generator and associated load) may be neglected and that attention may be focused upon the force-equilibrium equation of the mechanical elements of the regulator." Their whole analysis of regulator stability is based upon this assumption, and yet throughout the paper they always use as experimental evidence a system including both regulator and generator.

The error in this approach has been firmly established in the theory of servomechanisms and feed-back amplifiers. For it is known that one element in such a system can be inherently unstable and yet have the system remain stable. It is further established that all the elements in a system may themselves be stable and yet form an unstable system. To analyze regulator stability and then offer, as supporting proof, the performance of a regulator-generator combination, simply has no meaning. This objection can only be proved to be valid, of course, if the system in question satisfies the criteria necessary to apply servomechanism theory. At the Naval Research Laboratory this has indeed been shown to be the case; for reasonably large departures from the initial operating point both the carbon pile regulator and a d-c generator act essentially as linear amplifying elements in a closed loop system.

The authors have made static measurements of the force versus deflection characteristics of the spring and magnet. The spring and magnet deflections for which they experimentally found system instability are not totally unrelated to the positions for regulator instability specified in their theory. However, the proper relationship was not recognized in the paper. Consider for example the region of rising voltage characteristic which they obtained upon adding load. Consider, too, the portion of the stable region for which their stability criterion was not satisfied.

The experimental stability data which the authors had available all included a generator of some sort. The regulator and generator can both be considered as linear amplifiers in a single loop feed-back control system. As such each has a characteristic transfer function and amplification factor. When the amplification of the regulator grows large, the feed-back loop amplification becomes correspondingly large and the likelihood of satisfying Nyquist's stability criterion decreases. It has been shown that the carbon pile regulator has a monotonically increasing phase lag with increasing frequency. Furthermore, there is always some frequency for which its phase lag grows greater than 180 degrees. In addition, the phase lag of the generator increases with frequency. Therefore, there is always some finite amplification of the loop for which the system will become self-oscillatory no matter how infinitesimally small is the input disturbance.

How is this fact related to the authors' regulator stability criterion? The important slopes to consider are the magnet curve and the carbon pile curve rather than the magnet curve and spring curve as considered by the authors. When the carbon pile and magnet curves are parallel the amplification of the regulator is infinite. That is to say, an infinitesimal change of applied voltage gives rise to an infinite change of carbon pile re-

sistance. The feed-back loop amplification is then infinite and the system must surely oscillate as pointed out before. Fortuitously the carbon pile and spring curves are nearly parallel in the particular regulator analyzed by the authors. Therefore, the criterion they proposed is fairly good in accounting for the observed instability in this case.

The redesign of the spring which the authors undertook prevents the possibility of infinite amplification in the feed-back loop. This does not necessarily preclude the possibility of self oscillation of the system if the generator amplification is large, or if the time constants of the system are changed. The experimental work of the authors was done with a single generator, while it is well known from experience that a regulator which performs well on one system might be entirely unsatisfactory when in combination with a different generator.

The authors' answer to the stability problem has been an extremely critical change in the design of the regulator spring. In the past, mass production of these springs has proved to be an extraordinarily tricky task. It was by no means demonstrated in the paper that the trial-and-error cutting of the spring was practical on a mass production scale.

It seems to us that proposing critical changes in an already critical process is a basically wrong approach. The whole system should be analyzed, critical things made less so, and improvements made on those elements where more easily controlled changes can be accomplished.

W. B. Kouwenhoven and **G. J. Thaler:** The discussion presented by Mills and Scorgie is very interesting. Some of the factors mentioned by them deserve more consideration than has been given them. The authors wish to point out, however, that they were assigned the task of improving the performance of a given regulator with specific instructions that only a minimum number of changes should be made; also, the only generator available for testing the regulators had a very slow response. These limitations made it impossible to investigate many interesting possibilities.

The authors are not in complete agreement with certain specific statements in Mills and Scorgie's discussion. These are quoted and answered below:

1. . . . "To analyze regulator stability and then offer, as supporting proof, the performance of a regulator-generator combination, simply has no meaning."

The analysis was performed on a single regulator-generator combination in which the generator effects were obviously negligible. The resulting analysis certainly explains the performance of that specific unit and as such definitely has some meaning. It is true that generalization from such an analysis requires great care, but the discussion implies that the analysis will not permit generalization, and proof of this implication is lacking. On the contrary, the Westinghouse Electric Corporation has incorporated in their new regulator a coned spring with characteristics similar to our Belleville spring, and also have included a link-spacing adjustment. This seems to indicate that some of the results obtained from the analysis are applicable to other regulator-generator combinations.

2. . . . "However, the proper relationship (between magnet and spring deflections) was not recognized in the paper. Consider for example the region of rising voltage characteristic which they obtained upon adding load. Consider, too, the portion of the stable region for which their stability criterion was not satisfied."

The discussion fails to point out what is wrong and does not state what the proper relationship is. Mills and Scorgie then refer to two examples which are supposed to indicate a contradiction between the stated relationship and experimental results. They say first that a rising voltage characteristic is obtained upon adding load. If we refer to Figure 12 of the paper, which is the adjustment curve for the redesigned regulator using the Belleville spring, it is seen that the voltage at full load is always less than the voltage at no load (for the same speed) except at the end of the adjustment range where the magnet armature is pressing against the magnet yoke, and the unit is no longer operative as a regulator. The authors did not find a rising voltage characteristic upon adding load. The second condition referred to is "the portion of the stable range for which their stability criterion was not satisfied." Just what is referred to here is not clear, but the authors assume that it is the unstable region in the 4,200 rpm no-load curve Figure 12. This is not in contradiction with the stability criterion because, as specifically stated in the paper, the spring design was intended to approximate the magnet curve, and an exact match was not obtained. Perfect performance was not expected. The instability noted was due to a defect in the spring characteristic, not in the stability criterion.

3. . . . "Fortuitously the carbon pile and spring curves are nearly parallel in the particular regulator analyzed by the authors. Therefore the criterion they proposed is fairly good in accounting for the observed instability in this case."

It was perhaps fortunate that the authors worked with a regulator-generator combination in which certain effects were negligible. However, the implication in item 3, and also in item 2, is that the results obtained, and particularly the stability criterion have no value for other combinations. This is not so. Any regulator-generator combination should be stable when the generator load and speed are constant, and no matter what generator is used with the regulator the combination will not be stable unless

$$\frac{dF_s}{dx} > \frac{dF_m}{dx} + \frac{dF_{cp}}{dx}$$

because if this equation is not satisfied no restoring force is set up when the armature of the magnet is displaced, and, therefore, any transient mechanical shock will produce instability.

It is true, of course, that a regulator which satisfies this equation may still be unstable under dynamic conditions when used with certain generators. It then becomes important to know whether stability can be obtained by adjusting the degree of inequality in the equation, or by added damping, or by limiting the permissible compounding in the generator, or by some more radical change. These matters were not studied by the authors.

4. . . . "The important slopes to consider are the magnet curve and the carbon pile curve rather than the magnet curve and the spring curve as considered by the authors."

This fact was recognized by the authors. It is implicit in the equations used. It is apparent in Figure 7 of the paper that the important relationship involves the magnet and the carbon pile curves. Neglect of the carbon pile curve in later discussion was deliberate and the reasons for doing so were specified.

5. . . . "The authors' answer to the stability problem has been an extremely critical change in the design of the regulator spring."

Actually the authors' answer to the stability problem was to satisfy a given equation and at the same time to make the magnet and spring curves parallel. This was specifically stated in the paper. The redesign of the spring to accomplish this more general requirement was dictated by the necessity of making the minimum possible number of changes.

Sensitive Relay Contact Protection Systems

J. P. DALLAS
MEMBER AIEE

T. H. McCULLY
NONMEMBER AIEE

Synopsis: A protective network for sensitive relay contacts can be expected to extend reliable operation to several million cycles of operation. This result is to be achieved only if the sensitive contact circuit current is limited. Peak current transients on closure are shown to be the critical factor rather than the system voltage as popularly supposed. A 120 volt d-c sensitive contact circuit is considered safer and easier to protect than a comparable 24-volt circuit. It is shown that inductive loads can be successfully protected to values of almost two times that permissible for a resistive load with the type of protective system under consideration. Design procedure is given for a 2-circuit polarized relay protection system estimated to weigh less than eight ounces. It is suggested that available polarized relays when used with the subject protective system will provide power sensitivity, accuracy, and reliability in excess of that available from comparable electronic amplifier equipment.

MANY aircraft electric equipment design problems when reduced to their simplest terms result in contact-making devices. Remote positioning; automatic temperature, pressure, and flow control systems; voltage regulation; and reverse current, over voltage, under voltage, and fault detection devices; often reach their ultimate simplification through the use of a simple contact making armature mechanically or electromagnetically coupled to the function to be controlled.

The field of application of such devices has been greatly broadened by recent technical progress. Problems of stability and the elimination of hunting in contact-making controls can be solved by the use of simple feed-back circuits for introducing velocity correction factors into the control relay circuit. Modulating control action accompanied by substantial increases in sensitivity and accuracy is now commonly obtainable in contact-making control mechanisms through pulsing techniques. Improvements in magnetic and contact materials and in the design of relay mechanisms have been responsible for a recent substantial increase in the sensitivity and accuracy of such devices. Sensitive relays designed to meet aircraft requirements for resistance to acceleration and vibration with sensitivities below one-half milliwatt are commercially available.

Lest our enthusiasm for sensitive contact making controls appears to exceed the bounds of good judgment and common experience we hasten to state that such devices in their present stage of development used without adequate contact protection systems are not suitable for many aircraft applications because of a serious lack of reliability. As a result of failures due to neglect of contact protection there has developed a consistent trend away from contact making devices in aircraft design. Voltage regulators have changed from contact making types to the carbon pile. Nearly all recent servo-mechanical developments have adopted the electronic mode of operation. In the past ten years almost every major aircraft electric equipment manufacturer has experimented with and abandoned contact making controls in favor of heavier and more complicated, but more reliable devices. It is the purpose of this paper to suggest that this may have come about largely as the result of a failure to investigate sufficiently contact making protection systems.

Paper 48-215, recommended by the AIEE air transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 19, 1948; made available for printing August 26, 1948.

J. P. Dallas and T. H. McCully are with the Hughes Aircraft Company, Culver City, Calif.

Causes of Relay Unreliability

If we assume adequate protection from environmental causes of failure by hermetic processing, then sensitive contact failures in operating inductive circuits occur for the following reasons:

Destruction of the Contacts Due to Arcing. This is usually the result of a gross misapplication or overrating of the relay and deserves very little comment. In general if there is visible sparking at the contacts, failure will occur in a few thousand cycles.

Metal Transfer. In an unprotected inductive circuit the energy stored in the inductance is dissipated in the contact gap when it opens. This results in erosion of the contact surfaces and the building up of a pointed protrusion on the surface of the negative contact. It can readily be seen that in dealing with gaps of the order of 0.005 of an inch, very little metal transfer could be tolerated.

Sticking or Welding of Contacts. Where reasonable caution has been used in the design this is the most common cause of failure. It is also the most unpredictable. Contacts may develop a tendency to stick at irregular intervals of many thousands of cycles of operation. The genesis of this type of failure as shown in Figure 1 is usually as follows: (1) through contact erosion and metal transfer the effective contact area of the surface is so reduced that the current density is increased to the point where welding of the two contact surfaces occurs, (2) since the contact separating forces are extremely low, microscopic welds can produce sticking. Subsequent breaking of the weld with increased signal is likely to again alter the surface contact area so that normal operation of the contacts will be resumed until a new minute protrusion of the negative contact again reduces the contact area, increasing the current density to where a weld again occurs.

Because this type of failure is dependent upon unpredictable changes in the contact surface, which vary with metallurgical imperfections in the contacts, mechanical wear, and electrical transients in the circuit; it is almost impossible to predict sensitive contact reliability in terms of ordinary testing procedure.

Unless contact erosion is effectively controlled, microscopic welds of the con-

Figure 1. Contact erosion and closure by action of d-c arc

tact surfaces requiring a measurable separation force can occur at almost any assignable current value. If we specify our maximum contact separating force at one gram, then experience shows that currents up to approximately 50 mils can be reliably handled as long as the contact erosion due to energy dissipation of the arc at the break is held to the minimum made possible by present contact protection systems, which come very close to entirely eliminating the arc at break.

Since the peak current upon contact closure is the critical factor, it is desirable to employ at least 120 volts in the contact circuit. The sensitive relay is usually called upon to operate a contactor coil having power requirements which are the same regardless of circuit voltage. It is obvious, therefore, that in order to hold the load current to a minimum, the supply voltage must be as high as practicably possible. For example, a currently available contactor with a 120-volt coil has 3,000 ohms resistance, which gives us a coil current of 40 milliamperes. This is well within the desirable maximum of 50 mills. This same relay with a coil wound for 28-volt operation would have a resistance of 160 ohms and a coil current of 170 mills, making the protection problem very difficult. Since the ampere turns requirement of a given relay does not change with coil voltage it follows that the stored energy will also be constant.

There is one other factor that makes operation at high voltages desirable. The load impedance for the same power requirement is much higher than for a low supply voltage. The effectiveness of a contact protection network is determined by achieving a small ratio of the contact protection impedance to the load impedance. This is much more readily achieved when the load impedance is high.

Contact Protection Systems

The object of contact protection systems is to provide a means for absorbing the energy normally dissipated in the contact gap when the circuit is open. In the simple resistive circuit of Figure 2, the voltage rise is almost instantaneous. An arc begins at point A and ends at point B. The arc duration will be of the order of one millisecond. It is to be noted that the jagged peaks on closing are the result of contact bounce. While good relay design should be aimed at eliminating contact bounce, it is not always possible to do so. For this reason, contact protection systems must be designed to take care of circuit transients resulting therefrom, and must be designed around the characteristics of the particular relay to be used.

The addition of a capacitor across the contact as shown in Figure 3 is the first step in contact protection. It will be noted that the entire energy of the contact opening is absorbed in the capacitor eliminating all evidence of arcing. When the contacts are closed the capacitor is discharged and a very high current peak is produced. For example, with a 40-milliampere 120-volt d-c contactor coil load all evidence of arcing at the break will disappear when the value of the capacitor is approximately a tenth of a microfarad. But the current peak through the contacts when they are closed may reach a value of several amperes which would be sure to weld the contacts.

In order to limit the peak current through the contacts to some safe value it is necessary to add a resistor in series with the capacitor as in Figure 4. Since the voltage appearing across the capacitor when the circuit is open is the full line voltage it becomes obvious that the series resistor r can be selected by Ohm's law to limit the peak discharge current to any desired value.

Contrary to general belief, contact protection for sensitive relay circuits is more difficult for purely resistive circuits than for inductive circuits. This is because the peak current appearing at the contacts when the circuit is closed as at A in Figure 4, is the sum of the normal resistive load current plus the discharge current from capacitor C through resistor r. It is obvious that if an inductive load were employed the instantaneous peak on closing would be much lower. The inductance would delay the rate of rise of the normal circuit current so that the instantaneous peak current would be substantially that determined by capacitor C discharging through resistor r.

For example, if the capacitor series resistor r of Figure 4 is gradually increased at some point close to the resistance of the load, the effectiveness of capacitor C in preventing an arc will diminish to the point where a visible arc will appear. If r is made approximately 0.8 of the load resistance R the best compromise between contact breaking arc suppression and circuit closing peak current will be affected. In the previous example, the normal load current would be 40 milliamperes and the peak current supplied by the capacitor discharge would be 50 milliamperes, so the total peak current at point A when the contacts are closed would be 90 milliamperes.

Referring to Figure 5, if exactly the same circuit constants are used but with the additional load inductance L, the time constant of this inductance will delay the

Figure 2 (left). A resistive circuit without contact protection

Figure 3 (right). A resistive circuit with simple capacitor contact protection

Figure 4 (left). A resistive circuit with R-C contact protection

Figure 6. An inductive circuit with R-C and germanium rectifier contact protection

rise of the normal circuit current of 40 milliamperes so that the peak current of the capacitor discharge does not add to the normal load current. The peak current transient at closing for Figure 5 will therefore be approximately 50 milliamperes instead of the 90 milliamperes which would occur with the pure resistance load.

Referring to Figure 6, germanium crystal diode rectifiers have been added across the load and across the R-C network resistor. The diode connected across the load dissipates the bulk of the energy stored in the load, effectively removing the peak voltage at the opening of the contacts. This has the effect of reducing an inductive circuit to a resistive circuit as far as the circuit performance at the instant of contact separation is concerned. This will have no effect upon circuit conditions at the instant of contact closure. The rectifier placed in parallel with resistor r in Figure 6 reduces the impedance of the protective network at the instant of contact separation. Therefore, the rise of voltage across the contacts at the instant of contact separation is greatly reduced below that experienced by the basic R-C protective network.

Design Procedure

Because of the many indeterminate variables inherent in a contact system, an empirical design procedure based on oscilloscope observation rather than mathematical analysis is the most practical way to design sensitive contact protective systems at present.

The basic design philosophy of any protective system intended to increase reliability must recognize that every added device carries with it inherent liabilities of failure as well as possible protective advantages and that where a protective system of several elements is proposed the separate liabilities of these elements must not add, or there will be little real gain in reliability. The design of a protective system should be aimed at securing the maximum of protection from the remaining elements of the system after the assumed safe failure of any one element.

With these ends in view the design of the system illustrated in Figure 6 should be undertaken in the following order:

1. The capacitor series resistor r in Figure 6 should be as high as possible without producing appreciable arcing on contact opening as determined by oscilloscope observation. A practical value of r for sensitive relay contact circuits not exceeding 60 milliamperes is approximately 0.8 of the load resistance. This resistance determines the peak discharge current through the contacts on closing by a simple Ohm's law relation.

2. The contact shunt capacitor value is determined by oscilloscope observation of the voltage and arc condition across the contacts and the peak currents observed in the contact circuit on closing. The equipment for making these observations is described in the Appendix and Figure 7. The capacitance is increased from zero to a minimum value that will eliminate contact arcing with r equal to about 0.8 of the load resistance. The capacitance required will be of the order of 0.01 microfarad. By increasing the capacitance above this minimum value the peak voltages appearing in the system may be reduced. Thus, in a typical circuit of the type discussed an increase of C to 0.2 microfarad reduced a peak voltage of 800 volts to 400 volts. A safety factor of two to three on the voltage rating of the capacitor is recommended.

It is to be noted that optimum adjustments for minimum peak current during contact bounce will not correspond to the adjustment for minimum peak voltage on contact separation, and the optimum value taking into account both conditions should be chosen. The primary reason for taking so much care with the design of the R-C contact protection network is to insure that it will have maximum effectiveness should the rectifier portions of the circuit fail or become inoperative. Since the best of rectifiers often leave something to be desired in the way of reliability, this is a necessary precaution.

3. The application of the rectifiers to the basic R-C protective circuit is as follows. The current passing through the rectifiers cannot exceed the normal load current because of the nature of the inductive property of the load. This is readily understood by pointing out that the protective network constitutes a bypass circuit around the contacts through which the normal current is rerouted at the instant of contact separation. It is the property of the reactance of the load to behave so as to maintain this flow of current. Various types of rectifiers have been investigated for this application, and the germanium crystal diode was found to be by far the most satisfactory for two reasons. It had very low capacity between its terminals, and therefore did not contribute to the peak discharge current through the contacts at the instant of closing. It is the only available rectifier that has a back to forward ratio exceeding one thousand.

Figure 5. An inductive circuit with R-C contact protection

Table I

	Ounces
Two 0.2-microfarad 600-volt oil-filled capacitors	3.00
Four *1N39* germanium crystal diodes	.57
Two 1-watt resistors	.25
Hermetic enclosure and plug mounting	3.56
Total weight, hermetically-sealed plug-mounted dual contact protection unit	7.38

The germanium rectifier that is most suitable for this application is known as the *IN39* crystal diode. Its maximum allowable inverse voltage is set at 200 volts direct current and under normal circumstances as applied in this circuit, the inverse voltage across either of the rectifiers will not exceed the supply voltage. The *IN39* has a rated peak anode current of 150 milliamperes.

If the foregoing procedure is followed, a protective network for the sensitive relay contacts will result which can be expected to extend reliable operation to several million cycles of operation. With available components the weight of a network system for a polarized relay with two contact circuits is shown in Table I.

Conclusions

A self-contained contact protection unit hermetically sealed which can be expected to extend the reliable operation of a sensitive polarized relay to several million cycles of operation can be constructed from available components at a weight of less than 8 ounces.

The critical design factor for a sensitive relay contact protection network is the contact circuit current. For present commercial sensitive relays 50 milliamperes is the desirable maximum.

It can be shown that with a given load power requirement, raising the voltage of the contact system will not change the amount of energy stored in the load which must be dissipated in the contact gap or absorbed by the protection system. This is true because the energy stored is proportional to the square of the ampere turns which is constant for a given contactor regardless of the supply voltage of the circuit. A protected 120-volt d-c sensitive contact circuit can safely handle more power than an equivalent 24-volt circuit. The effectiveness of a contact protection network is determined by achieving a small ratio between contact protection impedance and the load impedance. This is much more easily achieved in high-voltage control circuits.

Figure 7. Test equipment circuit

Inductive load circuits are easier to protect than resistive load circuits, and in general inductive loads can successfully be protected to values of two times that permissible for a resistive load. This is because current is the critical factor and the time delay in the buildup of the current in inductive circuits prevents the additive peaking of load and protective network discharge current.

Severe contact erosion through metal transfer to the negative contact will reduce contact gaps instead of increasing them because the deposited metal taken from a considerable area of the positive contact is deposited on the negative contact in the form of a protrusion. The contact area is diminished until current densities reach the welding value. For any given current this will occur at some physical dimension for the weld which will require a definite maximum separating force.

Appendix

The equipment used for measuring voltage and current transients in the contact system and for measuring the circuit parameters necessary for the design of the contact protection system, is standard laboratory equipment. Referring to Figure 7; in order to use a standard oscilloscope such as the Dumont *Model 241* which does not have a provision for satisfactory transient observation, it is necessary to provide for repetition of contact opening phenomena at some convenient sweep rate. To accomplish this, the sensitive relay under observation was driven by a square wave signal of approximately three volts, and at a frequency of about ten cycles per second. This method of observing contact circuit transients has the advantage of presenting to the eye or camera a picture of maximum transient values for a large number of cycles of operation.

Contact circuit voltage transients were applied directly to the vertical deflection plates of the scope. Contact circuit current transients were picked up from across a 10-ohm series resistor and applied to the vertical amplifier.

No Discussion

An Experimental Investigation of the Electrical Performance of Bolted Aluminum-to-Copper Connections

W. F. BONWITT
NONMEMBER AIEE

Synopsis: Bolted bus connections between bare aluminum and copper, with an electrotinned and flowed finish, will provide a low-resistance joint which will be reasonably stable even under extreme conditions of elevated temperature and corrosive attack. While the use of a compound, Penetrox "A," will greatly improve and stabilize the contact conditions, the combination of aluminum and copper (electrotinned and flowed), will form a satisfactory electric connection even when made without the use of any compound.

THE increased use of aluminum as an electrical conductor has raised the problem of suitable connectors, especially when connections have to be made between aluminum and copper. Since aluminum-to-aluminum connections offer no serious problems which have not been satisfactorily solved in one way or another, this investigation has been confined to the electrical performance of aluminum-to-copper connections.

The purposes of conducting this rather extensive investigation were to determine:

1. The feasibility of making direct connections between aluminum and copper.
2. The most suitable finish (plating) for the copper member of the connection (the aluminum member was always bare).
3. The effect of using a compound in such connections.

Obviously, the problem of making aluminum-to-copper connections is not confined to bolted bus-bar connections, such as were used for the experiments described in this paper. The problem of connecting aluminum conductors in the form of wire or cable to copper conductors of similar form, or to copper bus bars, is encountered even more frequently, and in this case, the connection is rarely a direct one, but requires the use of an intermediate member, a connector. The question then is: Should the connector be made from aluminum, or should it be made from copper or a copper alloy? And in the latter case, should such a connector be plated, and if so, which is the best finish?

It is easy to understand that the ideal solution would be a universal connector, which will work equally well with copper and aluminum. This has been recognized for a long time, and many attempts have been made to provide such a connector. At present, several copper, or copper alloy connectors are being offered for use with aluminum conductors. All these connectors have a finish (plating) on the copper base metal, and in addition, some of the manufacturers specify the use of a compound in making these connections between the aluminum conductor and the connector.

Since the practical experience with these connectors is as yet limited, it was found desirable to determine the most suitable finish or plating for the copper member of the connections, and the effect of different compounds on the electrical quality of these connections.

Experimental Data

In order to eliminate the unavoidable variables which are introduced when using actual aluminum cable and the proper connector, the experiments were carried out with bolted bus-bar connections between aluminum and copper, and the test procedure consisted of exposure of the test samples to elevated temperatures and to a prolonged salt-spray test.

Although the tests were made with bolted, direct connections of aluminum and copper bus bars, it is reasonably safe to apply the findings to bolted or clamped connections for other than flat conductors. The problems created by the use of aluminum in contact with copper are essentially the same, whether flat bar is concerned, or whether a stranded or solid round conductor is clamped in a connector: the galvanic dissimilarity of the two metals with its possible serious effect in the case of corrosion; and the comparative softness and ductility of the aluminum as compared to copper, with the possibility of cold flow, relaxation, and consequent reduction of contact pressure.

The test conditions were selected with the foregoing in mind. The heat treatment was thought to accelerate possible relaxation by repeated expansion and contraction of the connection, in addition to promoting possible formation of high-resistance oxides on the contact surfaces. The extended salt-spray test procedure, on the other hand, would provide extremely severe corrosive conditions. In addition, an extended, natural, ageing period, prior to the two test procedures, was included.

Separate test samples were used for the two test procedures. All test samples however were identical in respect to the design, material used, and their dimensions. Figure 1 gives a view of the test sample, and also the significant dimensions. Aluminum, as well as copper bars, were cut from mill lengths of bus bar, 1 by 1/4 inches. The aluminum (center) bar was always bare, while the various finishes were applied to the two end bars which were made from copper. Since the dimensions of the samples, as well as the

Paper 48-216, recommended by the AIEE transmission and distribution, and substation committees and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, October 5-7, 1948, Washington, D. C. Manuscript submitted May 24, 1948; made available for printing August 27, 1948.

Figure 1 (left)

Figure 3 (right)

(Bolts omitted)

hardware used, were alike, and since care was taken to apply the same tightening torque to all the samples, the contact pressure can be assumed to have been identical for all samples.

A tightening torque of 250 inch-pounds was applied to the bolts. Tests had shown that this torque would provide a contact pressure of approximately 3,000 pounds per square inch. This may seem an unusually high contact pressure, but since this determination was made immediately after assembly, and since the relaxation, especially in the case of the aluminum bar, is considerable, this value probably decreased rather rapidly in the immediate period following assembly.

The bolts and nuts, as well as the washers, were steel, cadmium-plated with the commercial thicknesses applied to such hardware. Bolts were 3/8, 16, $1^1/_4$ inches long. Washers were placed under the boltheads and nuts to provide a better distribution of the pressure, and while this may not be standard practice, it seems advisable in the case of aluminum connections.

There were seven variations of the copper bars. They were selected with a view of including the different finishes or coatings now being used on connectors for aluminum conductors, mainly cadmium and tin platings. A number of variations of these two basic platings were tested also. As a control, bare copper bars were included, and zinc-plated copper bars were added.

Following is a list of the various sample groups. The numbers given for each such group correspond to the actual numbers of the assemblies (see the test data record in the appendix, Tables V to XI). The odd numbers referring to samples tested at elevated temperatures, and the even numbers referring to the samples in the corrosion tests.

1. Numbers 1–6, bare copper, bright-dipped before installation.
2. Numbers 7–12, copper, cadmium-plated, 0.001 inch.
3. Numbers 13–18 copper, cadmium-plated, 0.0003 inch.
4. Numbers 19–24, copper, electrotinned, 0.0003 inch.
5. Numbers 25–30, copper, electrotinned, 0.0003 inch, and flowed.
6. Numbers 37–42, copper, hot tin-dipped.
7. Numbers 43–48, copper, zinc-plated, 0.0002 inch.

A few remarks regarding the finishes (platings) just listed shall be made here.

As mentioned before, the center aluminum bar was always bare, and no cleaning process was applied to this aluminum bar before assembly, except for a wiping with carbon tetrachloride to remove any possible dirt and grease. While it is realized that careful cleaning is frequently applied to aluminum before installation, and, as a matter of fact, should always be done, it was the intention from the outset to conduct the experiments under the most adverse conditions. Furthermore, while cleaning of flat bar is a simple operation, the cleaning of wires or cables is a different matter, and it is safe to assume that a large portion of the conductors are not cleaned prior to installation beyond the scraping action applied in removing the cable insulation.

The various copper bars were wiped also with carbon tetrachloride before assembly to remove dirt and grease. As far as the surface of the bars is concerned, and that is true for aluminum, as well as for copper bars, no particular finish was attempted. All bars were cold rolled, and their surface was in no way improved before use. Only around the drilled holes were the edges chamfered to insure good contact between the two bars.

Cadmium plating was tested in two thickness, 0.0003 inch and 0.001 inch because of the sometimes encountered opinion to the effect that this particular metal was only effective when applied in comparatively heavy layers.

As can be seen from the list, electrotin-plating was tested in two variations: as a regular electrotin deposit 0.0003 inch thick; and in flowed condition. The flowing process, which turned out to produce the best finish tested, was accomplished by plating the regular thickness of tin, and then immersing the plated sample into hot palm oil. The result is a conversion of the crystalline structure of the plating into an amorphous structure, this conversion resulting in a smooth, shiny surface.

The hot-tin dipping was done by dipping the samples into a 35-65 alloy of lead and tin. The thickness of the coating was not measured, but was, of course, much greater than that of any of the electro-deposited platings.

The zinc plating was tested since this metal was one of the first ones to be used in connection with aluminum, and zinc-plated aluminum connectors had shown good results in contact with copper.

Each of the seven variations listed was tested in three different manners, without a compound, with Penetrox "A" compound, and with a third compound, described subsequently and designated as "compound B."

In selecting these three variations, it was taken into consideration that a compound is more or less generally recommended for aluminum connections, but it was felt that any finish of the copper members of the connection, in order to be completely acceptable, should be satisfactory even if no compound was applied. It will be realized, that no matter how strongly the use of a given compound is recommended, there is no assurance that

Figure 2

(Bolts omitted)

Figure 4 (left). Comparative standing of samples after elevated temperature test

Figure 5. Comparison of samples after exposure to corrosive atmosphere

such a compound is actually applied before installation. This was the reason for testing samples without a compound.

Penetrox "A"[1] is a petrolatum-zinc compound and is recommended for all aluminum connections. Its functions are twofold: its metallic components penetrate the surface film of the aluminum (oxide), while the petrolatum acts as a protective coating to keep out moisture and to prevent oxidation of the contact surfaces.

Since it was realized that Penetrox "A" will not be used exclusively, "compound B" was tested also. This compound has been widely used for many years as an anticorrosive protection for electric connections, and is also a petrolatum base compound.

There are other compounds made and recommended for use with aluminum, but none of them were considered sufficiently tested for inclusion in this investigation.

Both compounds were applied in a uniform manner by coating (wiping) the contact surfaces of the aluminum and copper bars. No scratch brush or any other abrasive tool was used in this operation.

As mentioned briefly in the beginning of this paper, two test procedures were used: elevated temperatures; and salt spray. Identical but separate samples were used for the test procedures, and all samples were observed during a natural ageing period of 624 hours (26 days) after assembly, before undergoing either of the test procedures. The two test procedures are described subsequently.

1. Treatment at Elevated Temperatures

This test consisted of exposure of the test samples to various elevated temperatures for eight-hour periods. This was done for all samples simultaneously by placing them in a constant temperature air oven in such a way, that the bus bars would be supported in a horizontal plane. Such eight-hour exposures were made at:

Degrees Centigrade	(Degrees Fahrenheit)
75	(167)
100	(212)
125	(257)
150	(302)
175	(347)
200	(392)

These temperatures were kept within ±2 degrees centigrade, and resistance measurements were made on the samples after each such eight-hour run, after allowing the samples to cool at room temperature. The samples were placed in the oven at room temperature, and the oven temperature was raised to the respective values. This took from approximately 1/2 hour for the lowest test temperature, to approximately two hours for the highest test temperature, and the eight-hour period was started as soon as the test temperature was reached.

2. Corrosion Test Procedure

The second set of samples were used for the corrosion test which consisted of an extended exposure to a salt-spray atmosphere. This test was conducted for a total exposure of 1,000 hours, with resistance measurements made every 100 hours.

The samples were placed in a salt-spray chamber in which the temperature was maintained between 95 and 100 degrees Fahrenheit (35 and 37.8 degrees centigrade). The salt mist was generated from a 20 per cent sodium chloride aqueous solution by means of preheated air at a pressure of 15 pounds per square inch. This compressed air was saturated to avoid a so-called dry spray. The samples were supported in one horizontal plane so that the salt spray would not directly cover them.

It is apparent that both of these test procedures were extremely severe, and that they exceeded any reasonable service conditions encountered for aluminum connectors.

As mentioned repeatedly, only the electrical quality of the bus-bar connections was of interest in this investigation, as far as the performance of the connection was

21	Zinc-plated, dry	490.8	28.2	1640.4

concerned. This electrical quality is best represented by the resistance from one bus bar to the other. Therefore, resistance measurements were made on each assembly, as shown in Figure 1, from the copper bar to the center aluminum bar on both sides, thus providing two measurements for each sample assembly. The measuring distance was uniformly 3 inches, this distance comprising a 2-inch overlap and 1/2 inch each on the copper and the aluminum bar. Measurements were made at room temperature by means of a laboratory precision Kelvin bridge, and always corrected for a 20 degree centigrade reference temperature so as to be directly comparable. The current used for these measurements was ten amperes, and this current was considered small enough to disregard any possible temperature rise of the samples due to the measuring current.

Results

The observations made on the samples during the test procedures are given in the Appendix, in Tables V to XI.

Since the criterion of performance is the resistance of the various connections, these resistances are tabulated in Tables I and II, dividing the data according to the two test procedures, elevated temperature, and corrosive atmosphere.

These two tables show the initial and final joint resistances of all samples where the figures given are the mean resistances of the two identical connections tested on the same assembly (see Figure 1). In order to provide the first rating of the samples, they are arranged in the order of increasing final resistance. Order numbers are assigned to each sample, and these order numbers appear also on Figures 4 and 5, which show the standing of the samples graphically. These graphs give the relative conductivities rather than the resistances, so as to show the absolute, as well as the relative standing, of the samples.

Since a finish on the copper should provide satisfactory contact conditions even if no compound was applied, the final resistances have been compiled in Tables III and IV for the seven finish variations each as a group regardless of the compound used by taking the average resistance of the three compound variations, for example, no compound, Penetrox "A," and "compound B." The groups have been arranged in the order of increasing final resistance.

Similar to the procedure followed in summarizing the sample resistance, a bargraph (Figure 6) shows the performance of the seven finish-groups expressed by the relative conductivity. This graph shows not only the average final group conductivity but also the initial conductivity, thus giving the change of conductivity as well.

Discussion of Results

It is the object of this investigation to determine the most suitable finish for copper members of copper-aluminum connections. Furthermore, the best finish should be acceptable with respect to the electrical qualities of the connection, even when used without any of the compounds.

Tables III and IV, as well as Figure 6, show the foregoing conditions clearly. Disregarding the use of a compound, and simply averaging the resistances of the three variations tested of each finish, we find the three groups using tin as a finish to be the best. This is true for both test conditions, elevated temperature, and corrosive atmosphere.

Within the tin group, the flowed tin finish is the best, topping the list of all finish variations. All of these evaluations are based on the lowest joint resistance after test, which is equivalent to lowest contact resistance and highest relative conductivity.

Turning to the performance of individual samples, where the effect of the compound shows up, we find, as the most striking result, that the application of a compound results in a lower initial as well as final joint resistance on all samples regardless of their finish. Of a total of 21 samples used in each test procedure, the first 11 samples tested at elevated temperatures used a compound. And under corrosive conditions, the first nine samples

Figure 6. Effect of tests on sample groups

Shaded area indicates loss of relative conductivity due to test procedure

all had a compound applied. Distinguishing between the two used—Penetrox "A" and "compound B"—we see that Penetrox "A" is superior, especially under corrosive conditions (the first six samples had this compound). At elevated temperatures, there is little difference between the two compounds, as Table I shows.

While the preceding summarizes the comparative standing of the sample groups, the following covers the electrical quality of the connections as such. In other words, were the connections in all their variations good electrical connections, and how was their quality affected by the test procedures?

In order to discuss the quality of the connections, we first have to define what we consider to be a good connection. As stated at the beginning, we are only concerned with the electrical qualities of the connection, and we obviously want these connections to be good ones not only after installation but throughout the test procedures applied.

Since there is no generally accepted standard of a good electric connection, we will establish such a connection as one, which has an initial relative conductivity of at least 100 per cent (in other words, a connection with a resistance not greater than the resistance of a single conductor forming this connection). Furthermore, we do not want this initial resistance to increase more than about 50 per cent during any one of the test procedures, so that the final relative conductivity will not be lower than roughly 67 per cent. We have thus established two characteristics of a good electric connection, namely, its initial resistance level, (in relation to the resistance of the conductors forming this connection) and the permissible deterioration as a consequence of ageing (relaxation), and the two test procedures.

Using the preceding criteria as a yardstick, we find that the following samples meet the first condition, an initial relative conductivity of 100 per cent or better (in order of decreasing average):

1. Electrotin, 0.0003, Penetrox
2. Bare, Penetrox
3. Cadmium, 0.001, Penetrox
4. Electrotin, flowed, Penetrox, dry, "compound B"
5. Cadmium, 0.0003, Penetrox
6. Hot-tin dipped, Penetrox, "compound B"
7. Zinc-plated, Penetrox

It is interesting to note that this list contains all sample variations tested whenever Penetrox was used.

Applying the second condition of a relative conductivity of not less than 67 per cent at the conclusion of the test, the following samples meet this requirement, again in the order of decreasing average relative conductivity:

1. Electrotin, flowed, Penetrox, dry, "compound B"
2. Hot-tin dipped, Penetrox, "compound B"
3. Cadmium, 0.001, Penetrox
4. Bare, Penetrox
5. Cadmium, 0.0003, Penetrox
6. Electrotin, 0.0003, Penetrox

This second listing is identical with the

Table III. Average Initial and Final Group Resistances

Elevated Temperature

Order Number	Finish on Copper Bars	Joint Resistance, Microhms Final	Initial	Resistance Increase, Per Cent

Figure 7. Flowed-tin copper versus cadmium-plated copper, effect of elevated temperature

Figure 8. Flowed-tin copper versus cadmium-plated copper, effect of salt-spray test

first one, except that the zinc-plated samples dropped out because of failure in the elevated-temperature test. The failure of electroplated zinc in respect to its electrical properties at higher temperatures is well known.[2]

If Penetrox is used, all finishes tested (even no finish at all on the copper bar) will provide a satisfactory connection with the bare aluminum, with the single exception of zinc as a finish. However, we stated at the beginning of this paper that a finish in order to be fully acceptable as a coating for copper, should perform satisfactorily even with no compound applied at all. It can be seen from the two listings, that only a single finish met this condition, namely electrotin, flowed.

Since cadmium is used as a plating on copper, or copper alloy connectors to make them suitable for use with aluminum conductors, the performance of this metal as a finish on copper is of particular interest.

Figures 7 and 8 show the performance of cadmium-plated samples versus electrotinned and flowed samples, during the entire test as expressed by the relative conductivity of the connections.

As pointed out before, the application of Penetrox makes every finish satisfactory, and the cadmium-plated samples are no exception and they are as good as are samples with the flowed tin finish. However, the performance is strikingly different when samples without a compound, or with "compound B," are compared.

It is interesting to note that there is a definite trend of reversal of the relative conductivity as a result of the elevated temperature. This is particularly noticeable when "compound B" is used, although in general it applies to Penetrox also. This reversal seems to show that the contact resistance is reduced as higher temperatures are being applied.

There is another characteristic of cadmium-plated samples worth mentioning, that is, the high, initial resistance level of the samples, regardless of the thickness of the plating. When Penetrox "A" is applied, this resistance is reduced to a normal level, but in the case of samples without any compound and of samples with "compound B," the values are so high that the group resistances show this characteristic quite strikingly (Figure 6).

Since the resistance of cadmium is fairly low (lower than that of tin), and since it is quite unlikely that the metallic components of Penetrox "A" could penetrate a plating even 0.0003 inch thick, this behavior of the cadmium-plated samples can be explained only by the presence of a high-resistance surface film which is penetrated by the Penetrox "A" compound.

Conclusion

The results have in themselves shown that a satisfactory electric connection can be made between bare aluminum and copper. Furthermore, the results showed clearly that the electrical quality of such a connection can be maintained at an acceptable level through an extremely severe test procedure, both in respect to elevated temperatures and under corrosive conditions.

The following conclusions are based on the results given previously and also on the visual examination of the test samples as given in the Appendix:

1. The samples using tin as a finish for the copper member of the connections stood up better than samples with any of the other metals used, and were superior also to bare copper samples.

2. Within the sample groups using tin, the group with a flowed tin finish was the best.

3. The use of a compound between the contact surfaces will have a much greater effect on the level of the contact resistance and its stability than the finish on the metal.

4. Flowed tin was the only finish tested which produced satisfactory contact conditions throughout the test even when used without a compound.

5. Appearance of corroded samples and especially of their contact surfaces is misleading. A clean, bright surface does not necessarily indicate good electrical contact conditions (low-contact resistance).

6. The potential difference between two

metals forming an electric connection or their relative standing in the galvanic series should not be overestimated. In the presence of a compound or possibly even a lubricant only, the performance of the bare copper-aluminum samples was surprisingly good.

Appendix

The observations made on all test samples are compiled in Tables V to XI inclusive. Since the data contained in these tables form the basis for the conclusions reached, a few explanatory remarks are given. These explanations seem necessary since the tables contain more than just the observed resistances of the test samples.

The test data have been arranged in seven identical tables, one for each sample group. Each table thus contains all the data for a given copper finish with and without the use of a compound, and for both test procedures, including the ageing.

Observed Resistance

The first column in each of the three divisions (no compound, Penetrox "A," "compound B") of each table gives the observed resistance of the joints as it was observed at the different stages of the test. The figures given are the means of the two observations on each sample assembly. The second column shows the increase of the observed resistance, and these two columns do not seem to warrant any further comment, except for the general statement that the consistency of the observations on the two joints forming one sample assembly was always good, and it was in every case permissible to average the two observed values.

Relative Conductivity

Since the observed resistance in itself is not a significant characteristic of the quality of a joint, the third column in the tables gives the electrical relative conductivity of the connection.

Relative conductivity is a significant

measure of the quality of the joint with respect to its electrical resistance. It is expressed as the ratio between the resistance of an imaginary (or real) conductor with the same dimensions and made from the same material as individual members forming the joint, and the actual joint resistance. Thus, if the relative conductivity of a joint is 100 per cent, this indicates that the joint has a resistance equal to the resistance of the unbroken, single conductor of the same dimension and made from the same material. Similarly, a relative conductivity of 10 per cent would indicate that the joint resistance is ten times the resistance of the unbroken single conductor of the same dimensions. For the purpose of computing the relative conductivity as given in the table, the resistance of the reference conductor was determined in the following manner, which is illustrated also in Figure 2.

The joint resistance was measured from P to P_1 across a distance of 3 inches (see Figure 1). The bus bars forming the joint were 1 by 1/4 inches each. The overlap distance was 2 inches and was centered within the 3-inch total measuring distance. The reference conductor therefore as shown in Figure 2 would be a single bus bar, with a measuring distance (P–P_1) of 3 inches. Since the joint is between aluminum and copper bars, we can imagine the reference conductor to be composed of two equal lengths, $1^1/_2$ inches of the measuring distance of aluminum, and $1^1/_2$ inches of copper bar 1 by 1/4 inches in area. The resistance of such an imaginary bar would then become:

$$R = \frac{r_{al} \times 1.5}{0.25} + \frac{r_{cu} \times 1.5}{0.25}$$

where

r_{al} = resistivity of hard rolled aluminum, or 1.1134 microhms per inch at 20 degrees centigrade, equal to 60.97 per cent International Annealed Copper Standard (IACS).

and

r_{cu} = resistivity of hard rolled copper, or 0.6969 microhm at 20 degrees centigrade, equal to 97.4 per cent IACS

Substituting the foregoing constants,

$$R=\frac{1.1134\times1.5}{0.25}+\frac{0.6969\times1.5}{0.25}=4.182+6.68$$

$$=10.862 \text{ microhms at 20 degrees centigrade}$$

The value of 10.86 microhms was used in the tabulations for the computation of the relative conductivity.

Contact Resistance

The fourth and last column in the tables gives the contact resistance of the connections.

Before discussing the method by which the contact resistance was determined, a brief definition of the term is given.

The total resistance of an overlap joint such as discussed here, can be broken down into three different partial resistances:

1. The metallic resistance, which is entirely a function of the particular metal used and its dimensions. Of course this resistance depends also upon the temperature at the time of observation, but this can be disregarded in this discussion since all measurements are corrected for the reference temperature of 20 degrees centigrade.

2. The resistance in an overlap joint which is due to the distortion of the current flow, the streamline effect. This resistance is independent of the physical properties of the conductors, and is determined by the configuration of the joint, that is the sectional area of the conductor, and the length of overlap.

3. The contact resistance, which is the resistance that the current has to overcome in order to pass from one bar to the other across the facing surfaces. This resistance is dependent upon several factors, such as the finish and preparation of the contact surfaces, the contact pressure, and the possible presence of a compound. Since it is generally accepted that current passes between two members of a joint at a number of more or less isolated points, there is an added resistance (included in the over-all term of contact resistance) due to the constriction of the current flow.

It is evident that the metallic resistance can be calculated since the resistivities of the metals and the dimensions of the bars are known. The effect of the streamlining of the current due to the overlap joint can be approximated by data which have been established for such bus bar joints.[3] In this particular investigation however, the effect of the streamlining has been determined experimentally as will be discussed

later on. The contact resistance, and that is the resistance listed in the tables, can then be determined as the difference between the measured resistance, which is the sum of all three partial resistances, and the sum of the metallic resistance plus the streamline resistance.

We shall now discuss how the sum of the metallic resistance plus the streamline resistance of an overlap joint such as was used for the experiment discussed here, can be determined by a simple experiment with a model connection. In Figure 3, two models are shown, one being the same overlap joint as used in test (A), the other being a solid block of metal having the same dimensions as the overlap joint (B). As was stated earlier, the streamline resistance is independent of the material and resistivity of the component parts of a joint.

Therefore, if we have determined the added resistance due to current flow distortion for a particular configuration we can use this value regardless of whether we deal with copper-to-copper, aluminum-to-aluminum, or copper-to-aluminum connections. It becomes evident that if we measured the resistance of the solid block (B) which has exactly the same dimensions as the joint (A), the same hardware and the same measuring distance, then this resistance is the sum of the metallic resistance plus the added resistance due to streamlining.

Further, if we now consider the resistance of joint (A) consisting of two separate bars made from the same material and also from the same material as the solid block (B), then this resistance contains just one more item, and that is the actual contact resistance.

All the previous considerations have been made under the assumption that the two bars are in intimate contact, which can be assumed considering the comparatively small contact area and the comparatively high contact pressure. The resistance of the solid joint can be measured, and models can be made from aluminum and from copper. The imaginary resistance of a solid copper-to-aluminum joint then becomes the mean of the resistance of the copper joint and the resistance of the aluminum joint, since streamlining is not dependent on physical properties of the conductors used. Then, if we deduct this resistance from the measured resistance of any of our samples, the difference is the contact resistance.

This contact resistance in the tables is given per square inch. The reason for this was to make comparisons easily possible with data available in the literature on contact resistance. Otherwise, since all samples had the same contact areas, the total contact resistances would have been equally comparable. In the following the actual figures, as they were determined on the models, are given. These figures were checked against the easily computed

Figure 9. Flowed tin, no compound

Figure 10. Flowed tin, Penetrox "A"

Figure 11. Flowed tin, "compound B"

Figure 12. Bare copper

metallic resistance and data on the streamline resistance available from investigations on this subject. It was found that the actually measured resistances were in close agreement with the computed values.

Measured resistance $P-P_1$ on model B (copper), microhms, 6.925
Calculated resistance, microhms, 6.349
Difference due to distortion of current flow microhms, 0.576
Resistance of identical model (B) made from aluminum instead of copper, microhms, 11.063

Average of resistances of copper and aluminum models

$$\frac{6.925+11.063}{2}=8.994 \text{ microhms}$$

A resistance of nine microhms was used to compute the contact resistance in the tables.

Physical Effects of the Test Procedures on the Samples

An investigation of the character covered in this paper would hardly be complete without thorough examination of the appearance of the bus bars, especially as they were affected by the prolonged corrosion test. Such an examination was made of representative samples and they are shown in Figures 9, 10, 11, 12, and 13.

Even superficial examination of the samples at the conclusion of the test showed two marked effects: samples tested at elevated temperatures had discolored completely depending on the finish of the copper bars (the aluminum bar which was always bare had mainly darkened more or less uniformly). Probably the darkest color was shown by the zinc-plated samples. Bare copper stood up comparatively well with only slight dulling of the initially bright surface. Cadmium also remained fairly clean, but the electrotinned samples changed to a rather dark color.

The effects of corrosion were strikingly apparent on all aluminum bars. Since aluminum is anodic, it is natural that it would corrode rather than the cathodic, protected copper.

Figures 9, 10, and 11, show the contact surfaces of electrotinned and flowed samples after conclusion of the test procedures. The samples tested at elevated temperature have been arranged on top of the corroded samples. Referring to these three illustrations, samples tested at elevated temperature show some spotted areas on the copper, but of course no corrosion. On the corroded samples, deep pitting is especially noticeable at the edges and in the center of the aluminum bar. On all samples the area of intimate contact is clearly visible around the holes and between them, and the copper bars still show some of the flowed-tin coating left.

Samples with "compound B" always remained comparatively bright and this was true regardless of the finish on the copper. While the preserving qualities of this compound are excellent, it lacks the penetrating properties of Penetrox "A," and therefore does not produce the low-contact resistance of the latter.

Figure 12 shows bare copper in contact with bare aluminum, the upper sample (number 4) with Penetrox "A," the lower sample (number 6) with "compound B," both after corrosion. The serious pitting of the aluminum is clearly shown on the aluminum bars, and again the "compound B" sample shows the well-preserved copper surfaces. Yet, the average joint resistance of the "compound B" sample at the end of the test was approximately 50 per cent greater than the resistance of the Penetrox samples.

Figure 13 shows the flowed-tin coating with a magnification of 500. The top illustration was taken on sample number 25, which did not have any compound and was tested at elevated temperature. On this photograph, the bottom area shows the copper bars. The white area in the center represents the flowed tin coating, while the top layer is copper plating which had to be applied in preparation of the sample for the metallographic examination. It can be seen that this tin layer is well preserved and continuous. The bottom illustration was taken from sample number 28 after the corrosion test. This sample also had a flowed tin finish and Penetrox "A" compound. The tin layer is still visible, but it is quite thin and not continuous.

Figure 13. Flowed tin (500× magnification)

The heavy dark layer between the tin and the top copper very likely consists mainly of corrosion products. There is a dark line approximately 1/32-inch thick alongside the bare copper on both flowed tin samples. This line indicates probable diffusion of copper into the tin, possibly as a consequence of the flowing operation. It is interesting in comparing these two photomicrographs to note that the joint resistance of the two samples was practically alike.

Discussion

C. S. Beattie and S. C. Killian (Delta-Star Electric Company, Chicago, Ill.): This paper makes a worthwhile contribution toward a more complete understanding of the long debated aluminum-to-copper contact question. Bonwitt is to be congratulated on his paper and on the very complete variety of protection tested. He has not, however, tested many samples of the same kind. Not until several dozen tests are made on one combination and averaged, can we rely on the result.

From Table I of the paper, Effect of Elevated Temperatures, it is noted that the final resistances varied from 9.0 microhms to only 19.5 microhms for the first 16 combinations tested. While we can say that one combination has twice the resistance of the other, the actual resistances are so minute that a difference of 9 microhms is microscopic and is of no practical consequence. Also since all 16 of the values are so very close to one another, it is very possible that a larger number of tests or a slightly different method of contact preparation on the same combinations might completely rearrange the table. It is also interesting to note that the cadmium-plated combinations had the largest decrease in resistance at the elevated temperature.

In Table II, Effect of Corrosive Atmosphere, the spread between the first 13 final resistances is not large, 11.4 to 26.4

microhms, a total difference of only 15 microhms. There is little to choose between these in actual practice and again it is interesting to note that the cadmium plated combinations 15 and 16, though ending at 58.2 and 60.9, started at 53.5 and 54.3 microhms, a total rise in resistance less than many of those combinations ranked above it. We know from many years of actual field experience that these cadmium combinations are quite stable and over years of time will continue to stay stable while those ranked higher in the author's table might continue to increase in resistance if the tests were run longer than 1,000 hours. If the cadmium-plated combinations using compound "B" were prepared according to recommended practice, the actual resistances measured would be considerably lower than those indicated in the table.

While a current of only ten amperes as used in the tests does keep down temperature rise, and save laboratory corrections on resistance measurements, larger currents might produce very different results. It has been shown that the resistance of corroded joints falls with an increase in current. The capacity of a 1/4 inch by 1 inch bar is far in excess of ten amperes and it is possible that the test should have been conducted at current values more nearly approaching those encountered in actual practice.

The data submitted in the paper represent an enormous amount of work and again assures the industry that a reliable copper-to-aluminum connection can be made if ordinary precautions are taken. Further testing and years of service experience under adverse atmospheric conditions may some day point to the one best method of preparing the aluminum-to-copper joint.

W. F. Bonwitt: The comments by Beattie and Killian are appreciated. Before discussing them, it should be stated that the tests described were made to obtain a comparative grading of the various platings or coatings under more or less controlled laboratory conditions. They were not intended to replace or eliminate observation in actual service. Such tests are being conducted with the best samples obtained from the original tests. For this reason and for obvious practical considerations, the number of identical samples was held to a minimum. However, the agreement between identical samples was so close in all cases that the small number of samples was not considered to impair the significance of the results too much.

As far as the effect of elevated temperatures on the resistance of these samples is concerned, it is quite correct that these effects were almost negligible for a majority of the samples. However, it was mostly true for samples which had a compound applied and this fact seems significant. The only coatings which performed satisfactorily even without a compound were hot tin dip, electrotinned, and electrotin flowed.

As far as the effects of the corrosion procedures are concerned, there is no doubt that cadmium is quite stable, maybe even more so than other coatings tested. However, this is more than balanced by the fact that cadmium, except when used with Penetrox "A," produces consistently a very high resistance level, while the tin group as a whole will be satisfactory even in dry condition. This is important from the practical point of view since the application of a compound is something which cannot be completely relied upon. It should also be considered that a 1,000-hour continuous corrosion test under the conditions described is extremely severe. It is impossible to estimate just how many years of service under various atmospheric conditions this would equal, but to judge from the appearance of the aluminum members, the author has rarely seen aluminum connectors or conductors with many years of service which were in a similar state of disintegration. Since the resistances of the samples of the tin group were still well below the resistances of the samples of the cadmium group after such a severe test, I feel that it is fair from a practical point of view to rate the tin above the cadmium, despite the fact that the cadmium samples were more stable.

As to the question of conducting the tests at such loads that a substantial temperature rise would have resulted, past experience has shown that the great experimental difficulties of such an arrangement when dealing with large numbers of samples, are in no proportion to the difference in the results obtained. However, in conducting field tests with the combinations selected as a result of the tests, proper consideration was given to such experiments.

The Naval Ordnance Laboratory Six-Trace Cathode-Ray Oscillograph

P. L. EDWARDS
NONMEMBER AIEE

TESTING of ordnance often requires the recording of high-speed steady-state and transient phenomena both in the field and laboratory. The portable multichannel magnetic-string type oscillograph is admirably suited for recording many signals simultaneously, but does not possess the high-frequency response, the high-input impedance, or the high sensitivity often required. A natural consideration is the use of amplifiers for overcoming these difficulties. An amplifier can easily have the high-input impedance and the high gain necessary, but for the over-all pass band to be wider than two or three kc requires that the amplifier be carefully compensated. The undesirability of a large direct current flowing through the magnetic-string element at all times and the usual instability of high gain d-c amplifiers often dictate that this be an a-c amplifier. Even with a carefully compensated amplifier, the upper frequency limit is about ten kc per second.

The use of cathode-ray tubes as the indicating elements of recording oscillographs is another approach to the solution of these problems. These tubes may be used over a very wide frequency range, and though almost always requiring amplifiers, these amplifiers need a flat frequency response rather than the complicated response required to compensate for the magnetic-string elements. Recording oscillographs have been in use for a number of years. However, those available during the recent war for recording several signals simultaneously were ordinarily very large and bulky, making field use difficult, if not impossible.

The Naval Ordnance Laboratory six-trace cathode-ray oscillograph *6TCRO* is a portable, general purpose oscillograph designed to eliminate the previously mentioned difficulties. With this instrument it is possible to record six signals and two timing traces simultaneously. Six 2-inch cathode-ray tubes are each driven by a high-gain high-input impedance d-c amplifier with a flat amplitude response to 40,000 cycles per second. Two additional 2-inch tubes are employed for recording timing signals which are internally produced. The indications of the cathode-ray tubes are recorded on a moving strip of 35-millimeter film.

Design work on the *6TCRO* was begun in the summer of 1944 and was essentially finished by early 1946. Ten units built by the laboratory were completed in 1947. Subsequent application has proved its utility, and has resulted in such a demand for use of the instrument by various government laboratories that a contract is being processed for construction of additional units.

In this paper shall be considered the electrical block diagram, Figure 1; the physical arrangement of parts, Figures 2, 3, 4, 5, and 6; the different modes of operation; and finally some of the uses for which the instrument has been employed.

Electrical Circuits

Figure 1 shows a circuit block diagram for the *6TCRO*.

The power supply (see also Figure 2) consists of electronically regulated +460 and −340 volt supplies and an a-c regulated accelerating voltage supply. The a-c voltage stabilizer also regulates the filament voltage for the tubes of the first stage in the amplifiers. The power consumption is 500 watts at 115 volts and 60 cycles per second.

Each amplifier (see Figures 1, 3, and 4) has a single-sided input into the first stage, a common-cathode-resistor phase inverter,[1] which drives the second push-pull stage. The second stage drives the horizontal deflecting plates of the cathode-ray tube. Each d-c amplifier has a gain of 8,000, an input impedance of 0.1 megohm, and a frequency response which is flat from zero to 40,000 cycles per second and is down 6 decibels at 100,000 cycles per second. The well-regulated power supply, the regulated filament voltage on the first stage, plus a careful selection of tubes has led to an amplifier relatively free from microphonics and with a spot drift, after a warm-up period of 30 minutes, of less than 1/4 inch in 20 minutes.

Each channel has individual controls for gain, intensity, focus, and vertical and horizontal positioning. The gain can be varied so that from 0.01 to 250 volts rms will give full scale deflection. There is also a common intensity control. Since the phosphorescent screens of the cathode-ray tubes are damaged in time by intense electron beams, the beams are normally deflected off the tube faces by means of a voltage applied to the vertical deflecting plates. When the clutch to engage the film drive is operated, a switch is closed which removes this voltage and positions the spots for recording. For preliminary adjustments, a toggle switch in parallel with the clutch switch is used to center the beams.

A means for voltage calibration of the channels is contained within the *6TCRO*. The output of a "parallel-T" sine-wave oscillator,[2] Figure 1, may be attenuated to any desired value, measured by an internal vacuum-tube voltmeter, and applied to the inputs of the amplifier channels. A switch is provided so that the

attenuated output of the oscillator may be fed into the amplifiers without the need for external leads.

For timing purposes, the output of the oscillator is clipped, amplified, and applied to the two timing cathode-ray tubes previously mentioned. The oscillator frequencies, and thus the timing frequencies, may be 40, 200, or 1,000 cycles per second.

Physical Arrangement

Figure 2 shows the *6TCRO* in use. The main recording unit is on the table and the power supply is beneath the table. Two power cables connect the recorder to the power supply.

The main unit, including a 24-pound cover not shown, weighs 190 pounds and is 22 by 22 by 23 inches. The power supply weighs 80 pounds and is 10 by 15 by 18 inches.

Figure 3 shows a cross section of the main unit. The light from the eight cathode-ray tubes, six for recording and two for timing, is reflected by the recording mirror to a Baltar 25 millimeter focal length lens which focuses the light from the fluorescent spots on the moving 35 millimeter film. For viewing, the light is reflected from the large view mirror to the small view mirror and from there to the rotating mirror which provides a visual sweep if desired.

Figure 4 shows a rear view of the front panel. The cathode-ray tubes for the timing traces are mounted on the two end channels (calibration channel and beam-control channel) and the tubes on the other channels are for signal recording.

Figure 3 (below). Main-frame layout

Figure 4. Rear view of front panel

Figure 6. Side view of main recording unit

(a) Camera; (b) mechanical timer for drum operation; (c) drive motor and Graham variable-speed transmission; (d) port for viewing tube spots; (e) manual clutch control; (f) front panel and channel controls

The amplifiers and end channels are each complete in a 5 by 10 by 2 inch chassis unit. The manner in which the amplifiers and end channels are mounted on the front panel and in the main unit is also indicated in Figure 3. The end channels are connected to the amplifier units by means of wires attached to lugs on both ends of the amplifiers and end channels, Figures 3 and 4. The amplifier-channel connections are made in this manner so that the replacement of a faulty channel may be easily achieved.

Figure 5 shows a front view of the main recording unit with the front panel, and the chassis mounted thereon, removed. The permalloy cathode-ray tube support acts as a shield against magnetic fields. The flash lamps are used for photographing title cards. These cards, regular 3 by 5 inch index cards on which record titles have been written are mounted in a slot in front of the cathode-ray tube faces, Figure 3. A capacitor is then discharged through the flash lamps and the cards are photographed, thus providing a permanent title on each record.

Operation

There are essentially two modes of operation of the moving-film camera. In continuous operation 100 feet of film are available for recording at film speeds of 1/3 to 12 feet per second. In drum operation, 10 inches of film are available for recording at speeds of 1/3 to 38 feet per second. The ease with which the 10-inch strips of film may be processed makes it desirable to use drum operation wherever possible. However, the choice of continuous or drum operation depends on these factors: the film speed necessary to resolve the signal; the duration of the signal; and the feasibility of synchronizing the signal with the recording period of the oscillograph. With drum operation the total recording period at the slowest film speed is $2^1/_2$ seconds; at the fastest film speed it is only 20 milliseconds. With continuous operation the recording period may last up to five minutes.

Figure 5. Front view of main recording unit with front panel removed

(a) Permalloy support for cathode-ray tubes; (b) rotating mirror; (c) flash lamps; (d) oscillator chassis; (e) manual clutch control; (f) clutch; (g) camera; (h) motor and Graham transmission drive; (i) film-speed dial and control

The mechanical timer, Figure 6, was developed for use with drum operation of the camera to aid in the synchronization of the recording interval and the signal. An integral part of the timer is a switch which may be used to initiate the phenomena to be studied. This initiation may be made to occur at any reasonable time during or before the period of recording.

Often there are short-duration signals to be recorded that cannot be synchronized as indicated before, and another method of synchronization is necessary if drum operation is to be used. Auxiliary equipment is now being developed at the Naval Ordnance Laboratory which automatically synchronizes the recording

Figure 7. Sample oscillogram

This oscillogram shows the usefulness of the instrument as used for both sequence-of-events timing and quantitative pressure measurements. Trace A is the 1,000-cycles-per-second square-wave timing signal. The second timing trace is not shown. Trace B is an amplified version of trace C to show the rise time; trace D is an amplified version of trace E. Trace F shows the primer flash signal, the only part of the oscillogram that has been retouched, and the time recoil begins. Traces C, E, and G are the output of strain-gauge pressure gauges fed directly into the 6TCRO while traces B and D have an additional stage of amplification

period with the occurrence of the signal. Th signal to be recorded is used to switch on the beams while the signal is also delayed electrically and introduced into the amplifiers after the beams are centered.

Conclusion

The six-trace cathode-ray oscillograph has been in use at the Naval Ordnance Laboratory for about two years, and has seen a great variety of uses during this period. The high-frequency response has made possible the recording of short-duration phenomena of the order of 200 microseconds, such as the impact of a steel hammer on a steel anvil, and the pressure-time curves of underwater explosions. The absence of phase and amplitude distortion in the low frequencies, as is present in a-c amplifiers, has made possible the faithful reproduction of long-duration transients. The high sensitivity of the channels has made possible the recording of the output of strain gauge circuits without additional amplifiers. The instrument has also been very useful in the determination of the time sequence of various complicated phenomena. Figure 7 is a sample oscillogram.

The high sensitivity, good-frequency response, high-input impedance, and convenience of operation has led to a demand for the instruments for a variety of uses both by the various sections within the Laboratory and by other government laboratories.

A Precision Electrothermic Voltmeter for Measurements Between 20 and 20,000 Cycles

F. L. HERMACH
ASSOCIATE AIEE

AN INSTRUMENT has been developed at the National Bureau of Standards primarily for standardizing voltmeters over a wide voltage range at audio frequencies. It is an electrothermic voltmeter of the thermocouple type, with an adjustable resistor in series with an insulated-heater, evacuated thermoelement. It is intended as a transfer standard, with its indications referred to a standard cell by means of a d-c potentiometer. In conjunction with a suitable potentiometer it can be used for measuring alternating voltages from 0.4 to 400 volts, at frequencies ranging from 20 to 20,000 cycles per second with an accuracy of 0.01 per cent or better.

The Transfer Principle

The basic electrical units are established at national standardizing laboratories in terms of the units of a concordant mechanical system, by means of experiments which are used to assign values to groups of standard cells and resistors. With such standards and by means of the potentiometer and its accessories, measurements of direct voltage, current, and power are made. The measurement of the corresponding a-c quantities depends primarily on certain types of electrical instruments which ideally have the same response on alternating current, for the defined a-c units, as on direct current. Such instruments, when calibrated with direct current and then used on alternating current, become standards which, in effect, transfer the units from direct to alternating current. Electrodynamic transfer instruments have been highly developed at the National Bureau of Standards for precise measurements and for standardizing other instruments at power-line frequencies,[1,2,3] and corresponding electrostatic instruments have been developed at the National Physical Laboratory.[5,6]

If an instrument is arranged to permit frequent calibrations on direct current, long-time stability or freedom from drift, low temperature influence, low losses, and other normally desirable characteristics become of secondary importance and the instrument may be designed and constructed to secure the best possible frequency characteristic. Such a transfer instrument need not have a scale in the ordinary sense at all, and may be designed for an increased sensitivity of reading by methods that would not be applicable to instruments intended for general use.

Description of the Voltmeter

Several types of instruments were considered for laboratory use as a transfer voltmeter at audio frequencies, and a thermocouple instrument, with a thermoelement in series with an adjustable resistor, was chosen as being most suitable over the necessary voltage range. The frequency limitations of such an instrument were carefully studied. All known sources of error were analyzed, and the magnitudes of the a-c–d-c differences which might result were at least roughly computed. Then, to guard against the possibility of appreciable errors from unsuspected causes, the instrument was tested by comparing its a-c–d-c performance with that of other types of instruments which might serve as transfer standards.

A voltmeter composed of a resistor in series with a thermoelement can be correctly used as a transfer instrument over the range of frequencies for which the output electromotive force of the thermoelement is constant for a constant applied voltage. This will be true if the response characteristic of the thermoelement, $E = f(I)$, and the effective impedance, $Z = V/I$, are each constant over the frequency range, where I is the rms current through the heater and V the rms voltage applied to the combination. The response characteristic of the type of thermoelement used in this voltmeter was believed to be suitably constant for frequencies well into the megacycle range, and the low-frequency and d-c response were verified by special tests which are described in the next section.

In order that the effective impedance of the voltmeter be independent of frequency, it is in effect necessary that no appreciable fraction of the current entering the heater be diverted through the thermocouple circuit. For the voltage-measuring device connected to the thermocouple in this instrument, it would be difficult to assure this with direct-connected thermoelements, in which the heater and thermocouple are electrically connected. Fortunately, suitable thermoelements in which the heater and thermocouple circuits are electrically but not thermally insulated by a small ceramic bead are available in milliampere ranges. Thermoelements may be constructed in which the capacitance between the two circuits is less than 1 micromicrofarad, insuring negligible capacitance currents through the apparatus connected to the thermocouple, at frequencies far above the range planned for this instrument. Such an evacuated thermoelement, with a single junction of the thermocouple in

Paper 48-218, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 20, 1948; made available for printing August 26, 1948.

F. L. HERMACH is with the National Bureau of Standards, Washington, D. C.

thermal contact with a straight-wire heater, is used in this instrument.

An effective time constant of 1×10^{-7} or less and a skin effect of less than 0.01 per cent are necessary for the circuit from the points of voltage measurement through the resistor and the heater of the thermoelement, to insure constancy of the effective impedance within 0.01 per cent at frequencies up to 20,000 cycles per second. The values of time constant and skin effect for the straight-wire heaters of the type of thermoelement used in this instrument are well below this, so that the upper frequency limit is set by the series resistor. A commercially-available, shielded, audio-frequency decade resistor, modified to have two decades of 1,000 ohms per step and one decade each of 100, 10, and 1 ohms per step, all in series, is used in this voltmeter. The time constant of the circuit, computed from values of the equivalent series inductance and direct shunt capacitance of the resistor, is less than 5×10^{-8} at 20,000 cycles per second for each setting of each decade. The skin effect is also negligible for each decade. The adjustable series resistor is connected as a 3-terminal resistor, as shown in Figure 1, since for this connection the errors caused by the capacitances to the shield, which might otherwise amount to 0.1 per cent if the shield were tied to a resistor terminal, are considerably reduced. For example, calculations of the effects of the distributed capacitance of the resistance windings to the shield and of the capacitance of the studs and their connecting wires to the shield showed that by this connection the change in impedance over the range would be reduced by a factor of about four and would cause an error of less than 0.005 per cent at 20,000 cycles per second. The rotary switch brush of each decade is connected to the next decade of higher resistance, so that for the 3-terminal connection the current through the brush-to-shield capacitance of the highest decade is merely a load on the source. Additional computations showed that the brush-to-shield currents of the lower decades, including the middle 1,000 ohm-per-step decade, would cause errors of less than 0.002 per cent for switch capacitances as great as 10 micromicrofarads.

This study indicated that for each setting of the dials the effective impedance would remain constant within 0.01 per cent or less for frequencies up to 20,000 cycles per second. The actual frequency limit is somewhat beyond this upper limit at which this voltmeter will be used, and is set by the shunt capacitance of the highest decades. This shunt capacitance is apparently largely in the switch, and made it impossible to use a 10,000-ohm-per-step decade in this resistor. Such a decade would otherwise be desirable, and may well be feasible by special design.

A 30-milliampere evacuated thermoelement was chosen for this instrument, and was mounted in a phenolic enclosure at the end of the resistance box. A reference level of heater current of 20 milliamperes for which the electromotive force of the thermoelement is 6 millivolts, was selected. This is comfortably within the 24-milliampere limit of the highest decades of the resistor, and the maximum power dissipation of eight watts at the rated voltage of 400 volts is not considered excessive.

For convenience of reading and for portability, the indicating element in the usual thermocouple voltmeter is ordinarily a pivoted d-c instrument. Although satisfactory for most purposes, such an instrument would not have the required sensitivity for this application. Millivolt potentiometers have long been used with thermocouples in the measurement of temperature. However, since the voltmeter is used solely as a transfer instrument, the output electromotive force of the thermocouple need not actually be measured. Thus a potentiometer, while convenient, is not absolutely necessary, and for this instrument a rudimentary potentiometric circuit of Poggendorf's second or constant-resistance type,[4] which has since become known as a Lindeck element, was constructed. With this circuit, the greater portion of the electromotive force of the thermocouple is balanced out by the voltage drop in a 10-ohm resistor, leaving only a small voltage difference to be read on the "partial scale" of the galvanometer which completes the circuit. This arrangement in effect constitutes an elementary form of deflection potentiometer.

In use the series resistor of the voltmeter is adjusted to keep the heater current near a selected reference level so that the partial scale can be calibrated directly in per cent of the total indication. This is very convenient for the measurement of small voltage differences, as in a transfer test of another instrument. The scale is calibrated by observing the indications for two successively applied direct voltages differing by a small percentage, as measured with a potentiometer connected in parallel with the instrument. Such calibrations need be made rather infrequently. For an alternating-voltage measurement, as in an a-c test of another voltmeter, the series resistor is adjusted for any convenient indication on the partial scale and the direct voltage for the same indication is then measured with a d-c potentiometer.

The Lindeck element was primarily designed to have adequate stability. A number 6 dry cell is used as the source and two commercially-available helically-wound adjustable resistors of 100 and 5,000 ohms permit adjustment of the balancing current (0.6 milliampere) within 0.001 per cent. Repeated tests showed that contact resistance variations are negligible and that the changes in the voltage drop across the 10-ohm manganin resistor are less than 0.02 per cent during an hour.

A reflecting, wall-mounted galvanometer with a straight, linear scale, and a special thermofree key,[4] complete the thermocouple circuit. For the small differences (up to 1 per cent) normally encountered in a transfer test, the approximations involved in the use of such a scale, in place of a nearly quadratic scale to fit the response of the thermoelement, can easily be justified. No precautions other than the use of the special key were taken to guard against changing extraneous thermal electromotive forces. The

Figure 1. Schematic diagram of voltmeter circuits

sensitivity of the voltmeter depends, of course, on the characteristics of the galvanometer, and amounts to about 1 centimeter change in deflection for a 0.1 per cent change in applied voltage.

Tests of the Voltmeter

The first tests of the completed instrument, made with direct voltage, verified that ample sensitivity could readily be obtained and that the drifts were negligible for the types of thermoelements and for the circuits used. After a warm-up period of a minute, the changes in the indication of the instrument did not exceed 0.01 per cent in 15 minutes, and indicated that no extensive thermal precautions would be necessary under usual laboratory conditions.

Early measurements had indicated that with direct current through the heater, the electromotive forces of all thermoelements tested were dependent to a slight extent upon the direction of current flow. This was true even for insulated thermoelements of the type used in this voltmeter, in which no heater current flows through the thermocouple. Differences in electromotive force ranging from less than a hundredth up to a few tenths of a per cent have been observed for the two directions of the same magnitude of current flow on direct current. Tests verified with high precision that these differences caused no appreciable a-c–d-c errors provided the mean of the indications for the two directions of current flow was used as the d-c reference. The tests were made by connecting a pair of thermoelements in series and measuring their comparative a-c–d-c differences at a convenient audio frequency. When the mean of indications on direct current was used as the reference, the comparative a-c–d-c differences were in general less than 0.001 per cent, even for those pairs for which one thermoelement had a small and the other a large reversal difference. Exceptions were noted only when one particular thermoelement, which had a difference on reversal of about 0.2 per cent was used in the measurements. The tests together with the results of the tests described in the following paragraphs, indicated that this element had an a-c–d-c difference of about 0.05 per cent, which would make it unsuitable for use in this voltmeter. The measurements indicated the desirability of testing each individual thermoelement in this manner before using it for precise work with direct current, for the a-c–d-c difference in this thermoelement was wholly unexpected. With this exception, however, the measurements indicated that in general, for insulated-heater thermoelements, no appreciable transfer differences should be expected even if reversal differences are considerable.

A laboratory-type, suppressed-zero, electrodynamic voltmeter,[1] designed for precise measurements at power-line frequencies, was used to verify the low-frequency performance of the thermal voltmeter by direct comparison of the a-c–d-c differences of the two voltmeters at 30 and at 60 cycles per second. The tests were made by connecting both instruments in parallel, properly setting the series resistor of each, then adjusting the voltage for the same deflection of the electrodynamic voltmeter on alternating voltage, direct voltage, and direct voltage in the opposite direction, and observing the corresponding indications of the thermal voltmeter. The settings were made in quick succession in the order indicated to eliminate the effects of any possible residual drifts in either instrument. From the averages of the readings of the thermal voltmeter on alternating voltage and on direct voltage the comparative a-c–d-c difference of the two voltmeters was computed. At least two such series of observations were made at each test point and the averaged results were corrected for the computed a-c–d-c differences caused by the measured inductance of the electrodynamic voltmeter. The residual differences in the transfer performance of the two instruments are shown in Table I. For convenience, each observed value is tabulated as the per cent difference in applied voltage necessary for the same deflection of the electrodynamic instrument on direct current and on alternating current at the indicated frequency, on the assumption that the thermal instrument was without transfer error. The residual differences were all less than 0.005 per cent of the measured voltages at these frequencies. Because of erratic fluctuations in the alternating-voltage source used, this was nearly the limit of measurement. The differences are negligibly small for all anticipated uses of either instrument.

The actual low-frequency limit of the thermal voltmeter is theoretically determined by the response of the thermoelement itself. When a constant value of direct current is applied, the heater of the thermoelement reaches an essentially constant temperature. When an alternating current is applied, the temperature of the heater varies cyclically about a mean value, with an amplitude which decreases with increasing frequency, because of the thermal capacity of the element. At frequencies high enough so that the cyclic variations are negligible, the temperature rise of the heater is independent of frequency, if skin effect is unappreciable. However, at lower frequencies the mean value of temperature on alternating current may not be the same, because of the departure from Newton's law of cooling and the change of heater resistance with temperature. Errors may thus be expected at very low frequencies. The tests showed these to be entirely negligible at power-line frequencies for the thermoelement used in this voltmeter, and the actual low-frequency limit at which errors become appreciable is very probably considerably lower. It is hoped to determine this by difference tests of thermoelements having very different thermal capacities. The effect is mentioned here to show that for electrothermic as well as for electrodynamic and electrostatic instruments, which are also used on direct current, there is a gap in satisfactory response at low frequencies which can be narrowed but not closed.

Table I. Comparisons Between the Electrothermic and the Electrodynamic Voltmeters

Frequency, Cps	Voltage, Volts	Observed Differences, Per Cent of Indication
30	120	+0.002
60	20	+0.004
	50	+0.005
	150	+0.003
	240	+0.002

Two portable electrostatic voltmeters having ranges of 150 and 300 volts respectively were compared with the thermal voltmeter over the full range of frequencies at these voltages. They were new pointer and scale-type instruments of exceptionally good design and construction, with scale lengths of over five inches. A-c–d-c difference tests similar to those already described were made at the full-scale voltage of each instrument, at several frequencies between 30 and 20,000 cycles per second. A low-power microscope, focussed on the pointer of the instrument, was used to increase the precision of setting the same deflection on alternating and direct current. By carefully tapping the instrument to reduce pointing uncertainties and by taking repeated series of determinations at each test point, an estimated accuracy of 0.01 per cent was attained. The observed differences in the transfer performance of each electrostatic instrument and the thermal instrument are shown in Table II. Here again, for convenience in

Table II. Comparisons Between the Electrothermic Voltmeter and Two Portable Electrostatic Voltmeters

Frequency, Cps	Observed Differences in Per Cent of Indication	
	150-Volt Instrument	300-Volt Instrument
30	−0.004	−0.004
100	+0.002	+0.004
300	+0.005	
1,000	−0.004	+0.010
3,000	+0.006	
10,000	+0.004	
15,000		+0.008
20,000	+0.002	−0.009

visualizing the results, each observed value is tabulated as the per cent difference in applied voltage necessary for the same deflection of the electrostatic instrument on direct current and on alternating current at the indicated frequency on the assumption that the thermal instrument was without transfer error. From this table it is evident that the differences were 0.01 per cent or less.

Standardizing Voltmeters

This voltmeter is used at the National Bureau of Standards primarily for standardizing a-c voltmeters at audio frequencies, including power-line frequencies. Two distinct types of such tests, transfer and a-c tests, are made.

Transfer tests serve to determine the frequency characteristic or frequency influence, referred to a base or reference frequency, of instruments which accurately respond to a range of frequencies. A-c–d-c difference tests of other instruments are the most important tests of this kind, but determinations are also made occasionally with 60 cycles per second as the reference frequency, for instruments which do not accurately respond to direct voltage. The tests are made essentially as described in the previous section. By taking observations in the order indicated all effects such as scale errors, temperature influence, drifts, and so forth, which are the same at both frequencies are eliminated, and only those which are frequency-dependent are observed. These are relatively permanent for a given instrument so that a single test of this nature is adequate and future tests need be made only at the reference frequency.

Straight a-c tests are usually made for instruments which accurately respond to only a narrow range of frequencies (as for example uncompensated moving-iron instruments for use at 60 cycles per second). They amount to, in effect, determinations of the voltage necessary to deflect the instrument to each of several scale points. Any future tests to determine the extent of subsequent drifts in the instrument must also be made at this frequency. Such tests are in general less convenient than tests with direct current, and give less information than a transfer test combined with subsequent d-c tests. Therefore the transfer test is usually more valuable than a straight a-c test for instruments which can be used with full accuracy on direct current.

Conclusions

The development and tests of an electrothermic transfer voltmeter have been described, and its application to voltmeter testing has been outlined. This instrument can be used with a suitable d-c potentiometer to measure alternating voltage at audio and power frequencies to an accuracy of 0.01 per cent or better. The transfer principle, upon which the use of this instrument depends, has been re-emphasized. The voltmeter shows excellent transfer performance, comparable over a wide range of frequencies to that attainable with the best laboratory-type electrodynamic instruments at power-line frequencies.

It may be constructed with comparatively inexpensive, commercially-available components. Its excellent performance indicates, therefore, the perhaps unsuspected potentialities of electrothermic instruments of this type.

The voltmeter is, of course, a special instrument, not generally suitable for ordinary direct measurements of voltage. Except for transfer testing, its use is somewhat slow and cumbersome, and requires a potentiometer and its auxiliaries. However, such a potentiometer is a practical necessity in any laboratory in which precise measurements of current, voltage and power are to be made. The same potentiometer could be used in place of the simple Lindeck element described in this paper, if it has a suitable millivolt range, so that in many laboratories only a good decade resistor and thermoelement need be provided in order to permit in addition the precise measurement of alternating voltages. Alternatively, small portable millivolt potentiometers with internal galvanometers of ample sensitivity are now available, and could be used with the series resistor and thermoelement to make a convenient, entirely portable transfer standard.

Performance of Portable Electrical Instruments in Magnetic Fields

A. E. PETERSON
NONMEMBER AIEE

Synopsis: A knowledge of the performance of electrical instruments in the presence of magnetic fields is of importance to their intelligent use. The present paper describes: a study of this problem as applied to portable voltmeters, ammeters and wattmeters; and a brief survey of such magnetic fields as might be found around certain laboratory or small-plant equipment. Only portable direct- and 60-cycle a-c instruments were studied; panel- and switchboard-type instruments, presenting problems of their own were not included.

Experimental Setup

Helmholtz Coils

FOR producing the required field about the test instrument, a pair of Helmholtz coils one meter in diameter, shown in Figure 1, was constructed. Each of the two coils contained two 55-turn windings of number 13 American wire gauge insulated-copper wire. With all turns in series aiding, this gave a 2-gauss field at the axis with a current of one ampere.

The coils were mounted on gimbals which allowed the axis to be swung to any desired azimuth and elevation. The instrument under test was set on a rotatable table in the middle of the coils, the table assembly being supported through the gimbal trunnions. By an arrangement of pulleys and drive cables, the gimbal-mounted coils could be rotated to various positions while the instrument table remained fixed in its original orientation in space. In this way the instrument was maintained in a fixed position with respect to the earth's field. Care was taken in construction to avoid the possibility of short-circuited turns in the bronze control cables.

No magnetic materials were used in the assembly. The only metallic parts were the windings, control cables for the table, and a pair of slip rings. All other parts were of plywood, masonite or bakelite, dowelled and glued together.

Measurements of alternating fields set up in the coil indicated the field to be uniform within three per cent in the volume later occupied by the largest of the instruments tested. This was a fifteen inch by fifteen inch by five inch "laboratory standard" voltmeter. The field measured at the center of the coil assembly checked the design computations within 3 per cent.

Metering and Control Equipment

Each instrument tested was placed in the field of the Helmholtz coils and its readings were compared with a shielded reference instrument placed well away from this field. To insure that the quantity measured in the test instrument would remain unchanged, the pointer of the reference instrument was set to coincide with the cross-wires of a fixed-position microscope. The test instrument was read with a hand magnifier.

For d-c work, the field coils and the instruments were supplied from separate batteries and controlled by suitable rheostats and potential dividers.

A-c studies required more elaborate equipment, in that it was necessary to adjust the phase of the field with respect to the current in the test instrument. For wattmeters, a separate phase adjustment was used to regulate the power factor shown by the wattmeter. For a-c observations, a motor-generator set was used having two 3-phase generators coupled to the same motor shaft. The stator of one generator could be rotated with respect to the other, giving one of the required phase adjustments. For the other phase adjustment, a small phase-shifting transformer was used as needed. Remotely controlled rheostats in the two generator field circuits, variable-ratio autotransformers and fixed-ratio transformers were used to adjust the voltages and currents. The phase angle between the Helmholtz coil field and the current in the instrument under test was determined by use of a wattmeter. The current in one circuit of the wattmeter was in phase with the current in the Helmholtz coils, the current in the other wattmeter circuit was in phase with the current of the instrument under test.

Methods of Field Measurement

Alternating fields were measured by placing a small calibrated search coil in the field and reading the pick-up voltage with an electronic voltmeter. The field was then computed from the formula

$$B = E/(\omega A N \times 10^{-8})$$

where

B = field in gausses, rms
E = coil voltage, volts, rms
A = effective coil area in cm^2
N = number of turns in the coil
$\omega = 2\pi \times$ frequency

The AN constant for the coil used was a little over 15,600, giving about one volt for a 17-gauss 60-cycle field.

The strength of direct magnetic fields and of rms alternating fields was assumed to be numerically equivalent for equal direct and rms alternating currents.

For measuring other direct fields about the laboratory a small commercial gauss meter was used; its sensitivity was two gausses per division, with one division equal to about two millimeters. These measurements were of lower accuracy than those on alternating current, but were adequate for their purpose—establishment of the approximate magnitudes.

Paper 48-219, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted July 20, 1948; made available for printing August 23, 1948.

Figure 1. Helmholtz coil assembly

Effects of Magnetic Fields on Various Types of Portable Electrical Instruments

By the use of the Helmholtz coil and its auxiliary equipment, described in the section on Experimental Setup, representative portable instruments of the types available in the electrical instruments section's laboratory of the National Bureau of Standards were tested for their performance in magnetic fields.

Selection of Fields for Study

Three field magnitudes were chosen for the tests: 1, 5 and 10 gausses. The first was used as being typical of the field to which an instrument might be exposed under ordinary laboratory conditions or where, in the vicinity of stronger fields, reasonable care was taken in its use. The 5-gauss field is that usually mentioned in manufacturers' literature relative to the shielding of their instruments. The 10-gauss field, an admittedly severe test, was used to study the effectiveness of the shielding of the better instruments; it did result in rather absurd readings for some of the unshielded ones.

Moving-iron a-c instruments were tested in a-c fields. Permanent-magnet moving-coil meters were tested in d-c fields. The work on electrodynamic instruments was confined to alternating currents and voltages and a-c fields. (Shielded instruments of the latter type display hysteresis effects on direct current the magnitudes of which depend on the previous magnetization of the shield. To describe these effects it would be necessary to state completely the previous magnetic history of the shield. This has not been attempted in the present paper. One generally corrects for such effects by taking the mean of reversed readings.)

Test Procedure

Each instrument was tested in the horizontal position.

A preliminary survey was first made to find the field directions for maximum and minimum effects. The field was then directed to produce the greatest effect; when indicated, the instrument was oriented also so that the earth's field would have its least effect. On a-c tests, the phase angle between the field and the instrument supplies was adjusted for maximum effect.

Each instrument was checked in zero-, 1-, 5-, and 10-gauss fields at low, middle and high scale points. Additional measurements in 2-gauss fields were made in some cases. For each condition, observations were made for reversed field effects. Half of the difference between the observed scale divisions—expressed in per cent of full scale—was taken as the influence of the field upon the instrument. Depending on the type of instrument, reversal effects were secured in one of three ways: by reversal of lead connections to the test instrument; by 180 degree rotation of the Helmholtz coils; or by reversal of the current through the Helmholtz coils.

Results of Tests

Figures 2, 3, and 4 give the basic results for the three types of instruments tested. The plotted points refer to the upper end of the scales. The field influence is expressed in per cent of full scale as defined in the preceding paragraph. The statements of accuracy shown on the curves were secured from manufacturers' literature. The stated scale lengths are approximate.

It should be noted that the curves of Figures 2, 3, and 4 refer to values taken near the upper end of the scale. Further data for lower parts of the scale may be summarized as follows:

1. For moving-iron instruments the influence of the external field, expressed in per cent of full scale, remained essentially constant over the scale. This would be anticipated from their "square law" response.

2. As might be expected, for permanent-magnet moving-coil instruments the effects, for a given field, were proportional to angular deflection, that is the current in the moving coil. Thus a field having a one per cent influence at full scale value had, very closely, a one-half per cent influence at half scale.

3. Electrodynamic instruments, especially wattmeters, yielded less consistent results than the foregoing two types. Since electrodynamic voltmeters and ammeters have a "square law" response similar to that for moving-iron instruments, it might be expected that they would be influenced by external fields as in (1) above; results with these instruments were not entirely consistent but were generally similar to those for moving-iron instruments. Wattmeters

Figure 2. Effect of magnetic fields on moving-iron instruments

Figure 3. Effect of magnetic fields on permanent-magnet moving-coil instruments

Figure 4. Effect of magnetic fields on electrodynamic instruments

gave rather inconsistent results at the lower parts of the scale. It was expected that the influence of the field would depend on the magnitude of the current in the moving coil and on its orientation relative to the applied field; this simple relation presumably was modified by the effect of the shields on the internal field distribution, and by the variation in angular size of scale division as determined by the instrument construction.

Stray-Field Influence on Instruments

In considering the magnitude of external field effects on instruments, it is helpful to express the influence in terms of the manufacturer's stated initial accuracy which, of course, does not take account of the influence of magnetic fields or other ambient conditions. Such a comparison shows the superiority of well-designed and properly shielded instruments.

From Figure 2 it appears that none of the moving-iron instruments, even though shielded, fall within their accuracy classifications in a 5-gauss field. Of the seven shielded meters shown, four came within their stated accuracy in a 2-gauss field. The unshielded instruments are marked on the graphs; the rest are shielded.

The performance of the permanent-magnet moving-coil instruments, Figure 3, was much better than that for the moving-iron instruments. It will be noted that these curves fall into two groups. The two instruments showing the larger effects had low-coercivity magnets; the others were either made with high-coercivity magnets or had heavy shields. The influence of a 5-gauss field was less than the manufacturers' stated accuracies for the latter instruments.

Electrodynamic instruments, Figure 4, were intermediate between the other two types. Of the six tested, the influence of a 5-gauss field was less than the accuracy figure for two instruments. Three of the others were within, or very nearly so, their stated accuracies in 2- to 4-gauss fields. The one unshielded instrument (so marked) showed up very poorly, of course, under this sort of test.

Use of Instrument to Detect Stray Fields

If its supply is sufficiently steady the instrument itself may be used to check

Table I. Maximum Measured Fields Near Electric Equipment

Equipment	Field in Gausses — Distance from Equipment, Centimeters: 5	10	20	30
Adjustable-Ratio Auto Transformer				
1. 0.5 kva	2.4	0.7	0.2

75 hp	20			5
275 kw (Generator)	10		4	
(Synchronous Converter)			10	

* This transformer was mounted immediately beneath a wooden bench top with the control wheel above the bench. Instruments on the bench would be subjected to the fields shown.

the presence of harmful stray fields. This may be done by noting any change in readings of the instrument for positions 180 degrees apart, for a number of orientations. Except for permanent-magnet moving-coil instruments (and for moving-iron a-c instruments in d-c fields) such a check may be made also by reversal of the leads to the instrument. It is best, of course, to locate the instrument outside of any disturbing field. If this cannot be done completely, one may locate an orientation so that a 180 degree change in position causes a minimum change in reading. This assumes that the external field will not change direction at a later time.

Typical Magnetic Fields About the Laboratory

Table I gives the results of a survey of stray fields around various "suspect" items used in the National Bureau of Standards. The tabulated values represent the maximum fields observed at the given distances; the various distances for a given item were not necessarily in the same direction nor were the orientations of the fields necessarily the same. The distances were measured to the nearest point on the case or frame of the item under test. Readily movable pieces were so located as to minimize the effects of nearby magnetic materials. The larger items were tested as they stood, though in some cases their stray fields were obviously distorted by nearby structural steel and steel panels.

Comments on Table I

Placing a portable instrument in the fields tabulated for the 5 centimeter distance would amount practically to placing the instrument in contact with the apparatus case or frame. This is because the internal working parts of an instrument are, on the average, within that distance from the outside of its case.

Of the apparatus surveyed, only the 7-kva adjustable-ratio autotransformer (item 3), the 1-kva voltage-stabilizing transformer (item 6) and some of the larger rotating machines showed fields as large as one gauss at distances of 10 centimeters (4 inches) or greater.

The observed stray fields were found to drop off very rapidly with distance from the source, although this might not be the case for similar equipment near magnetic materials, such as steel supports and panels. If the presence and source of stray fields are realized, portable instruments can often be placed so as to be in very weak fields. Means of roughly checking the presence of such fields are indicated in the section on Use of Instruments to Detect Stray Fields.

The conditions of use of item 3 in Table I—the 7-kva adjustable-ratio autotransformer—were of some interest. As mentioned in the note (Table I) it was mounted directly beneath a wood bench top, with its control wheel on top of the bench. Auxiliary portable instruments would ordinarily be placed on the bench top and would be in strong magnetic fields. (The pointer indication of an unshielded moving-iron voltmeter, with 135 volts applied, varied from 120 to 150 volts as the instrument was moved about on the bench top.) The strength of the stray field at a given point varied greatly with the condition of loading and the resultant current and amount of the winding in circuit.

It should be recognized that the foregoing survey is merely illustrative and may not be at all typical of stray fields encountered around other types of apparatus and in other places, particularly near conductors carrying large currents.

Conclusions

1. Permanent-magnet moving-coil instruments which have high-coercivity magnets, or which are well shielded, are usually not influenced by a 5-gauss field to an extent greater than the manufacturer's stated accuracy.

2. Shielded electrodynamic instruments generally were influenced, in a 5-gauss field, to an extent somewhat greater than their stated accuracies but were within this figure in 2- to 4-gauss fields.

3. All the moving-iron a-c instruments tested showed effects, in 5-gauss fields, greater than their stated accuracies. Most of the shielded ones were within these figures in a 1-gauss field.

4. Of the available equipment checked only the larger adjustable-ratio autotransformers, certain voltage-regulating transformers, and the larger rotating machines showed external fields that should be expected to affect nearby electric instruments.

5. Judged by fields found near equipment in the author's laboratory, it is to be expected that the fields encountered in ordinary applications of portable instruments generally will be considerably less than five gausses.

Discussion

H. B. Brooks (Consulting Electrical Engineer, Washington, D. C.): The author's paper is a timely one, for we need to be reminded of the possibility of errors caused by stray fields, sometimes from unsuspected sources. For example, a very troublesome case of discrepancy in measurements was finally traced to the stray field from a slide rheostat in which the wire was wound on an enameled steel tube. The variable-ratio voltage-regulating autotransformer, which has deservedly found widespread adoption, should not be placed close to instruments, particularly to those of unshielded types.

The author gives values of field strength at distances of 5 and 10 centimeters from moving-iron instruments. Inasmuch as two of the older classical type of unshielded portable permanent-magnet moving-coil instruments will affect each other's accuracy by nearly one per cent when side by side, and by nearly two per cent at the minimum separation with pole pieces facing each other, it would be of interest to know the corresponding figures for modern d-c instruments with high-coercivity magnets, shielded and unshielded, in the possible combinations, for several relative positions and for various separations.

A. E. Peterson: The tests outlined below were made to extend Brooks' original observations[1] to permanent-magnet moving-coil instruments of more recent design.

Five instruments were intercompared: *a* and *b* were unshielded instruments of the older type having magnets of low coercivity; *c* and *d* were shielded instruments of more recent design, having low or medium coercivity magnets; *e* was a shielded instrument having a high coercivity magnet.

The following results were secured for full-scale deflections with the instruments at minimum separation and pole-pieces facing each other:

The effect of *a* on *b* for such orientation amounted to 1.8 per cent.

Pairing *a* successively with *c*, *d* and *e* gave effects ranging from 0.1 to 0.3 per cent. The effect of *c* on *a* was approximately the same as of *a* on *c*, and similarly for the other pairs.

The effects of *c*, *d* and *e* upon each other, when similarly checked by pairs, amounted in every case to less than 0.05 per cent.

Exploration around the foregoing instruments with a small gauss meter showed some interesting results. A field of about 30 gausses was measured close to the case of instrument *a* adjacent to the pole pieces; this dropped to 5 gausses at about an 8 centimeter distance from the case. Fields around instruments *c*, *d* and *e* were less than 1 gauss, about the limit to which the gauss meter could be read.

Brooks' comments about the stray fields of tubular rheostats wound on steel tubes suggested their comparison with rheostats of nonmagnetic construction which previous tests had showed to have very small fields.

One rheostat, wound upon an enameled steel tube, and having 29 ampere-turns per centimeter at rated current, showed fields of about 6 gausses at 10 centimeters from the ends and from the sides. Another rheostat, identical with the other except that it was wound on a porcelain tube, showed only 0.2 gauss fields at similar locations. A third rheostat, wound on a nonmagnetic tube, but having a steel slider-bar and a steel tie-rod through its center, showed approximately 1-gauss fields at the comparable points.

Silicone Insulation in Submarines—Toxicity

H. P. WALKER
NONMEMBER AIEE

T. E. SHEA, JR.
NONMEMBER AIEE

Synopsis: The effects of temperature and operation time upon the production of noxious gases from silicone insulated electrical equipment under conditions of simulated submarine service are reviewed and some of the general problems of toxicity of burning insulation are discussed.

A previous paper[1] discussed the subject of silicone insulation as applied to Naval electric power equipment and concluded that one of the problems yet to be worked out was the toxic effect of the products of decomposition, if any, of silicone materials used for motor insulation. In this paper, the authors will present the results of tests recently completed on this subject, as well as discuss the general problem of burning insulation.

Shipboard electric installations present special problems for insulating materials that may not exist in shore installations. As Naval vessels are necessarily built to a high degree of compartmentation requiring forced ventilation and also have large capacity power plants installed in relatively small spaces, there is perhaps more insulation per cubic foot of available engine room space than exists in land installations. Many Naval vessels are complete cities in themselves. An electrical fire in a surface ship is extremely dangerous while an electrical fire in a submarine is a hazard. For this reason, all electrical insulating materials used in Naval vessels are at present carefully screened to determine their suitability at elevated temperatures and the effects of noxious gases produced on thermal decomposition of these materials.

All organic insulation (and some of the inorganics), when subjected to temperatures above their "curing" temperatures, produce volatiles, some of which may be toxic, and the degree of toxicity depends on the amount of material decomposed, the temperature of the heat source, the conditions of air circulation and supply, and the length of time exposed to that temperature.

Many tests have been conducted to determine the toxicity of laminated and molded insulation used commercially, as well as by the Navy.[2,3] The Bureau of Ships sponsored a number of these tests and others were conducted by commercial organizations. The objectives of these tests, procedures and results are too voluminous to discuss in this paper; however, they do prove that carbon monoxide was the most dangerous decomposition product present.

In order to determine the effects of temperature and operation time upon the production of noxious gasses from silicone insulated rotating electric equipment under conditions of simulated submarine service, the Bureau of Ships requested the Bureau of Medicine and Surgery to set up a test program to determine these conditions. This project was assigned to the Naval Medical Research Institute in August 1946 and was completed in December 1947.[4] Briefly, the test procedures were set up as shown in the following paragraphs.

Navy type class *A* insulated 3-horsepower 440-volt alternating current 3-phase squirrel-cage induction motors were selected for test purposes as representative types of motors for Naval service and because of their ease of handling. These motors were stripped and rewound with silicone insulating materials so as to give maximum temperatures.

All motors were tested in a high-pressure chamber located at the Naval Medical Research Institute. This chamber, containing 190 cubic feet of space, was gas-tight, and was provided with means of controlling the ambient temperature without introducing or withdrawing air during the test, thus closely simulating a submerged submarine.

Motors to be tested were secured to a motor test block inside the chamber. They drove a nonsilicone insulated d-c generator, by two pulley belts (Figure 1). The motors were powered from the 440-volt supply to the Institute. Motor loading was accomplished by controlling resistance banks located outside the chamber. Currents developed by both the motor and the generator were indicated on ammeters located outside of the chamber, and frequent readings, made at regular intervals, were recorded; voltages developed by the generator were similarly recorded.

Iron-constantan thermocouples, located as indicated in Figure 1, were used to record all test temperatures on a temperature indicating recorder (0 to 300 degrees centigrade range).

In giving motor specifications, it is customary to indicate the number of degrees rise above ambient temperature to be expected. However, since preliminary tests indicated that the production of toxic gases by silicone insulation is related to the true temperature rather than to the number of degrees rise, all motor temperatures are actual winding temperatures as recorded on thermocouple number 1. These winding temperatures are the observable "hottest-spot" temperatures (temperature rise by thermocouple plus ambient temperature).

Samples of chamber air, for analysis, were withdrawn at the start and the end of each test and at 24-hour intervals during the run. White rats were used in all tests except the final one in which two

Paper 48-220, recommended by the AIEE marine transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted July 21, 1948; made available for printing August 18, 1948.

H. P. Walker is with the Bureau of Ships, United States Naval Department, Washington, D. C., and T. E. Shea, Jr. is a Lieutenant Commander on the staff of the Naval Medical Research Institute, National Naval Medical Center, Bethesda, Md.

human volunteers were used. For each test eight normal rats were exposed, two to a cage, with adequate food and water (Figure 1). At the conclusion of each test, the rats were bled as soon as possible by cardiac puncture and the blood samples were analyzed for carboxyhemoglobin (COHb) in volumes per cent. Per cent saturation with COHb was calculated on the assumption that the CO capacity of rat blood is 21 volumes per cent. This assumption is supported by a measure of the hemoglobin content of normal rat blood. It is to be stressed that while the values for rat COHb were of toxicological significance, they were not to be regarded as a quantitative measure of the effect on human beings.

At the start of each test the chamber was sealed and placed under a pressure equal to 40 inches of water.

A total of seven (7) motors were tested at temperatures ranging from 50 to 300+ degrees centigrade (top burnout temperatures were believed to approach 650 degrees centigrade). Most test runs were continued for a period of 96 hours; however, several tests were terminated at the end of 72 hours due to various mechanical difficulties. The motors were rewound with silicone insulating materials by the Westinghouse Electric Corporation, the General Electric Company, and the Dow Corning Corporation, using silicone products as produced by the latter two organizations.

Test Results

From the results of the foregoing tests as reported by the Naval Medical Research Institute[4] and from the observations of the authors during the tests, the following points are significant:

1. The generator used for loading the motor never exceeded class *A* insulation temperatures, so it may be concluded that this machine did not contribute to the evolved gasses in the test chamber.

2. At no time during the tests did the oxygen content of the chamber fall below a safe limit, nor did the carbon dioxide content approach a harmful value.

3. Preliminary tests of silicone insulating materials showed that the noxious substances given off on thermal decomposition were carbon monoxide, carbon dioxide, phenol and formaldehyde.

4. The motor tests revealed that carbon monoxide was the only substance found in the chamber in medically significant concentrations. Its concentration varied as a function of motor temperature and time duration of the test. Terminal values of 110 ± 50 parts per million CO in air and 12 ± 5 per cent COHb in the blood are to be expected when motor temperatures (observable hot spot temperatures) range between 200 and 230 degrees centigrade. The complete test data are reported in Tables I and II and plotted in the curve shown by Figure 2.

5. Insulation temperatures in excess of 300 degrees centigrade, maintained for even short periods of time, constitute a hazard to health.

Discussion

Before the data reported by the Naval Medical Research Institute can be applied to the design of an electric plant for shipboard use, the factors of installed kilowatt capacity and operating time must be considered.

For security reasons, a fictitious submarine design will be discussed. Let us assume that a 20,000 cubic foot

Figure 3. Relation between observable average equipment temperature, hours exposure and COHb concentration

(floodable volume) space represents the interior of a submarine. Also, a silicone-insulated electric plant is installed with a maximum output of 2,500 kilowatt operating at an observable hot spot temperature of 200 degrees centigrade. A further assumption is made that 2,500 kilowatt load will result in a 24-hour battery rate, and that a 500-kilowatt load will provide a 96 hour rate.

Under the test conditions, data were obtained at intervals of 24, 48, and 72 hours, as well as 96 hours, as shown in Table I. Human COHb concentrations were calculated from actual rat COHb values measured during the test at the above intervals of time. This data is shown in Figure 3, and gives the relation between human COHb, observed temperature in degrees centigrade and time in hours.

A reasonable assumption can be made that for a 20,000 cubic foot volume submarine, the ratio of space and kilowatts is approximately the same as that of the test setup; namely 1:1. Therefore, for a 96-hour battery rate, the operating kilowatt of a 20,000 cubic foot space approximates 500 kilowatts at an observable temperature of 200 degrees centigrade. It is recognized that the weight of insulation used per kilowatt does not vary directly as the kilowatt is increased; however, as the operating kilowatt of a submarine is made up of many small individual motors, the above ratio of 1:1 of space and kilowatt is assumed to be correct.

As the battery rate is a fixed quantity expressed in ampere-hours, the kilowatt connected load will vary as a function of time. If several fictitious values of kilo-

Table III. Toxicity Concentrations—20,000 Cubic Feet Submarine

Load in Kilowatts	Operating Time in Hours	Estimated COHb Concentration in Per Cent 150 C	175 C	200 C	225 C	250 C	Insulation Weight Factor
500	96	7.0	9.0	11.5	14.5	18	1
1,000	72	8.0	12.0	15	12.0	25	2
2,000	48	8.0	12.0	18	24.0	30	4
2,500	24	3.5	6.0	10	16	22.5	5

Notes: 1. COHb values for 500 kw taken from Figure 2 are for 96 hours.

2. For all practical purposes the weight of insulation for 1,000 kw, 2,000 kw and 2,500 kw is the same as for 500 kw; both propulsion and auxiliary rotating equipment being considered. However, assuming that double the kilowatts will double the weight of insulation, the COHb values will be as shown.

3. COHb values for 500 kw at 24, 48, and 72 hours are taken from Figure 3.

watt load and time are selected, it is possible to determine the COHb concentration over a given temperature range as shown by Table III.

Conclusions

It may be concluded that properly cured silicone-insulated rotating equipment installed in submarines when operating at observable temperatures not exceeding 230 degrees centigrade continuous temperature does not constitute a health hazard up to 96 hours operating time submerged.

Insulation temperatures of the total installed rotating electric plant in excess of 300 degrees centigrade, maintained for even short periods of time, constitute a hazard to health; however, a single motor "burnout" in a given submarine installation is not believed likely to increase the total level of CO concentration to a dangerous value.

Surface ship installations of silicone-insulated electric equipment, where adequate ventilation and air replacement are maintained, are considered to be safe from the standpoint of CO evolutions regardless of temperature or "burnout" condition.

Functional Evaluation of Insulating Materials

K. N. MATHES
MEMBER AIEE

DESIGN of modern electric apparatus is placing increasing requirements on insulating materials. The demand for materials to withstand higher temperatures, higher speeds and other extreme design requirements is continually increasing. Moreover, insulating materials must now withstand more severe climatic conditions from arctic cold to tropical heat and moisture. Airborne electric equipment must withstand extremely rapid changes in ambient temperature and humidity.

Recent trends toward decreased size, weight, and cost have greatly increased the insulation problems. New materials with radically different properties involve new application problems. Methods of evaluating insulating materials should produce significant conclusions in terms of design and service requirements. It is the purpose of this article to consider the type of methods now in use and to describe ways in which these methods are being improved.

Evaluation work carried on in the past, and now in progress, takes many forms but usually will fit one of the following categories:

Type of Test	Quality Evaluated
Test on materials (varnish, mica, plastics, and so forth)	Properties of individual materials
Tests on component parts (coils, bars, commutators, and so forth)	Properties of combinations of insulating materials
Tests on complete apparatus	Simulated service
Service records	Actual service

These categories should be interrelated for maximum benefit. For example, tests on component parts may contribute to recognition of a need for tests of specific materials. Likewise, tests on individual materials may be used to limit the number of tests on component parts or complete machines. Insulation evaluation programs which include work in all four categories are most productive when each phase is designed to aid the understanding and significance of the others. Experience with such programs indicates that a functional approach must always be emphasized.

This may be relatively easy in tests on complete apparatus, but tests on component parts sometimes tend to lose significance and tests on materials may become so arbitrary that they are useless in determining the performance of insulating materials in actual apparatus.

Service Records

The most significant evaluation of insulating materials should, of course, be those obtained from service records. However, failures in service are often difficult to interpret since the damage may be so great that the evidence is destroyed. On the other hand, a temporary failure may leave so little damage that the failure cannot be located. Wherever possible, the following items should be incorporated in the failure reports:

1. Age, rating, type of machine.
2. Duty cycle—continuous, intermittent, and so forth.
3. Maximum temperature obtained in the winding or a temperature log if available.
4. Chronological log of insulation-resistance measurements and associated winding temperature. Measurements should be made at at least two different intervals after applying voltage—for example 1 minute, and 10 minutes.
5. Type of winding and location of fault.
6. Appearance of fault and insulation with pictures if possible. Color transparencies afford more contrast and detail than black and white pictures.
7. Amount of oil, dirt, linters, or other materials on surface of insulation and nature of attack on insulation, if any.
8. Unusual climatic or ambient conditions such as excessive heat, high relative humidity, severe dust storms, chemicals, iron dust, or other solid contaminants.
9. Unusual conditions preceding failure such as lightning storms, short-circuited lines or switching operations which might produce surges, or any other severe or unusual electrical condition.

Service records are most valuable when collected systematically over a period of years. But at best, service records are limited and are likely to suffer from incomplete data, lack of control, and chance failures. Nevertheless, service records can guide the more easily controlled tests on complete apparatus.

Tests on Complete Apparatus

Next to service records, tests on complete apparatus can give the most accurate indication of the performance of insulating materials. The apparatus can be run under various duty cycles and can be exposed before or during such cycles to various laboratory conditions, such as high-ambient temperatures, high-relative humidity, moisture condensation, salt spray or fog, water immersion and even blasts of dirt, iron dust, and so forth. Failure to operate usually constitutes the end point of such tests but it is customary to measure insulation resistance also.

Paper 48-221, recommended by the AIEE marine transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 21, 1948; made available for printing August 18, 1948.

K. N. Mathes is with the General Electric Company, Schenectady, N. Y.

Figure 1 (above). Wedge designed to apply both shear and compressive stress to bonded mica sheet

Figure 2. Slippage of two bonded mica samples in the wedge test

Voltage withstand and surge tests can sometime be used advantageously.

It may prove difficult to set up adequate or sufficient combinations of test conditions to meet the wide variety of service requirements. The size of the following list for only a few possible combinations serves to illustrate this problem.

1. Heat aging alone.
2. Moisture exposure alone.
3. Salt spray or fog exposure alone.
4. Heat aging plus moisture exposure.
5. Heat aging plus salt fog exposure.
6. Moisture exposure after contamination with dirt.
7. Salt fog exposure after contamination with dirt.
8. Heat aging plus moisture exposure after contamination with dirt.
9. Heat aging plus salt fog exposure after contamination with dirt.

Obviously, it is possible to select only a few of these test conditions. This selection should be based on types of conditions most likely to be encountered in service and the conditions under which the insulation is most likely to fail. Consideration should be given also to the effect of accelerated test conditions. In illustration, an extensive study of the effect of increasing temperature on heat aging of 1/4 horsepower motors has been made by Scott and Thompson.[1] This study illustrates also the statistical variations obtained in such programs. A minimum of 80 identical motors were needed to evaluate just one type of insulation system. Only heat aging was studied. The effect of moisture or other conditions would have required many more motors.

Tests on complete machines are of necessity restricted in scope or limited to small inexpensive apparatus. For large apparatus, tests on component parts such as coils may prove necessary.

Tests on Component Parts

Tests on component parts can be made under the same variety of test conditions as described for complete apparatus except that running conditions may be difficult to simulate. For example, it may be easy to apply a voltage between winding and ground and yet very difficult to obtain voltage between turns in the absence of the magnetic circuit. Mechanical factors such as vibration, centrifugal force, and so forth, are particularly difficult to simulate. Despite these restrictions, very useful and significant information can be obtained from tests on component parts.

Of course, many types and varieties of component parts are in use, however, and a comprehensive study of each with all of the possible types of insulating materials would be a long process and probably impracticable. Hence, the evaluation of the insulating materials themselves becomes necessary.

Table I. Comparison of Methods for Evaluating Moisture Resistance

** 7-strand 0.032-inch magnet wire cable deflected at center of 3-inch span until cracked. Cracks determined by measuring insulation resistance in water. Elongation in outer strand calculated from deformation at failure.

Tests on Insulating Materials

Tests on insulating materials are often considered to be of little significance in indicating actual performance to be expected. For example, a dielectric breakdown test on a liquid insulating varnish is of doubtful value, because varnish is always converted to the solid form in actual use and solvents are largely driven off during application. Some of the tests for insulating varnishes, are just minor variations of tests developed previously for surface finishes. In such tests, a thin film of varnish is formed on a thin copper panel (replacing the steel or wood panels used in the tests on finishes) and tested in this form, even though insulating varnish is practically never used as a thin film on metal but rather as binder, saturant or finish for other types of insulating materials. So long as insulating varnishes were used largely as surface finishes, the film tests were to some extent useful. Modern insulating varnishes, however, penetrate deep into the insulation structure to give protection throughout and to act as a binder for the structure. Film tests are useless in evaluating these characteristics.

Slippage tests on mica illustrate how methods can be used to evaluate really significant properties. In commutator service, mica insulation is subject to shear as well as compressive stress at operating temperatures. Pasted mica sheet for this purpose is tested conventionally between two metal plates under straight compression. In order to include the factor of shear stress, the simple wedge shown in Figure 1 was built. In Figure 2, the slippage of mica pasted with two different binders is compared as a function of seasoning time. The significant difference shown between these two binders has been confirmed by service experience.

Tests on Composite Samples

In order to bridge the gap between tests on materials, and tests on component parts, an additional method of test is being investigated. In this work, samples are made from combinations of materials, magnet wire and varnish, for example. Such samples need not look like any component part actually used in equipment but should follow the principles outlined below:

1. Insulating materials should be combined in a manner similar to the combination found in actual apparatus.
2. Samples should be simple, easily made and reproducible.
3. Samples should be designed in such a fashion that properties important in manufacture or use can be easily evaluated, quantitatively, if possible.
4. One basic form of sample should be adaptable to as many types of test as possible.

Magnet wire treated with varnish is an important part of the insulation system of most electric apparatus. The varnished magnet wire cable sample illustrates a composite sample developed to evaluate the combination of varnish and magnet wire. To make this sample, magnet wire—cotton, glass fiber, enamel insulated is machine stranded to a concentric 7-

Comparison of different magnet wire insulation treated with an oil modified alkyd varnish

strand cable (with 0.032-inch wire a 2-inch pitch is used). This cable is cut to length, varnish treated, and baked as needed. In order to represent deep coil sections, the cable may be taped with aluminum foil which prevents varnish penetration along the side but permits it at the cut end of the sample. Several varnished cable samples are pictured in Figure 3. Such samples can be used for a variety of tests listed below:

1. Rate of varnish cure (insulation resistance).

2. Solvent or varnish attack on enamel (insulation resistance).

3. Film continuity (dielectric breakdown after water immersion).

4. Varnish penetration (visual inspection).

5. Rigidity and cure (plastic deformation and creep).

6. Heat aging (elongation to film rupture).

Several of these tests have been discussed in a previous article.[1] To illustrate the advantages of tests on composite structures, two tests with the magnet wire cable can be discussed.

Film Continuity

Varnish treatment is intended to prevent the entrance of moisture and dirt within the varnished structure. Three types of tests have been used to indicate the suitability of varnishes in this respect.

1. Wet dielectric strength (varnish filmed copper panel).

2. Moisture permeability (varnish film).

3. Brass rod immersion test (time for failure with 125 volts of direct current applied between varnish-coated rod and salt or acid solution).

In these three tests, every effort is made to obtain a continuous film or the test is invalidated. In practice, however, a smooth film is difficult to obtain because of the rough nature of the underlying insulation surface. The ability of a varnish to film such a surface may be more significant in preventing the entrance of moisture or dirt than the properties measured by any of the three tests listed.

The cable sample (bent into a U and varnished) can be immersed in salt or acid water and tested in much the same way as the brass rod sample. In this instance, however, the small multiple insulated wire surface is characteristic of the surface of many types of apparatus. Such surfaces are much more difficult to film than smooth metal surfaces. In fact, from two to eight varnish dips may be needed to give film continuity with the cable sample depending upon the characteristics of the varnish. The filming characteristics of a varnish do not seem to correlate at all with dielectric breakdown or moisture permeability as shown in Table I. It is probable, that in the majority of applications, the film-forming properties have greater significance. Both the pigmented alkyd and the asphalt varnish have superior film forming properties as shown in Table I with the cable U test. Service experience with such pigmented alkyd and oil modified asphalt varnishes has been particularly good where exposed to moisture even though for these varnishes, the moisture transmissivity is relatively high and the wet dielectric breakdown is low. These tests confirm the principle that a sample using insulating materials in combination should be used to permit significant evaluation.

Heat Aging

When exposed to high temperatures for long periods of time, varnished structures become embrittled. The progress of this degradation is one of the most interesting and important characteristics of insulation. The mandrel flexibility test has been used to compare heat aging characteristics of varnishes. In this method, a 0.001-inch varnish film on a 0.005-inch copper panel is bent about a 1/8-inch mandrel after increasing periods of time at an elevated temperature (usually 125 degrees centigrade) until the film cracks. The varnished magnet wire cable sample can be used also to evaluate heat aging. A 4-inch long heat aged sample is supported on a 3-inch spacing and the center is deformed in increments until the structure cracks. Results for Formex samples treated with various varnishes are shown in Figure 4. The rate at which elongation (flexibility) decreases varies greatly with different varnish treatments. For example, the unmodified phenolic varnish treated sample (*c*) becomes somewhat rigid quite quickly but for a long period thereafter does not become more rigid. In contrast the other varnishes which are initially more flexible may with time become more brittle than the unmodified phenolic varnish.

In Figure 5, heat aging of magnet wire cable samples, made of Formex and cotton and glass-insulated wire, treated with an oil modified alkyd varnish is compared. With a different varnish, a different order of comparison may be obtained (that is, cotton may be very inferior, and so forth). The considerable effect of the wire insulation emphasizes again the importance of evaluating insulating materials in combination. Table II gives additional comparisons for various varnishes and compares these results to mandrel flexibility tests on varnish coated copper panels. The complete lack of correlation is apparent. Service experience again seems to correlate more with the evaluation of the magnet wire-varnish combination rather than with the tests on materials alone.

Conclusions

Methods of evaluating insulating materials and systems should have the following features:

1. It should be possible to interpret results so as to aid design or predict service performance.

2. A majority or at least a principal number of the factors involved in design or application should be included.

Many of the methods now used, particularly in the evaluation of insulating materials, cannot meet such a test. Two practical approaches to the problem can be suggested.

1. Tests on insulating materials or systems should be made up with specific design or service problems in mind.

2. Insulating materials often should be evaluated in simple combinations, characteristic of the way in which they will actually be used.

It is apparent that insulation evaluation will become more varied and complex if evaluation is to be more useful and significant. The need for this increased complexity may indicate inadequacy and limitations of existing material specifications.

Care should be used that this increased complexity of insulation evaluation tests does not increase the burden of material specifications, which at present often limit, unnecessarily and undesirably, the design engineer in the choice of materials. These material specifications are best written so as to control or identify materials as manufactured or purchased.

Discussion

G. L. Moses (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Mathes is to be complimented on his objective approach to this very important problem in evaluating insulating materials. I heartily concur with his philosophy. It is quite important that we distinguish between tests which evaluate the performance characteristics of insulations and those tests which are intended merely as identity checks. It is therefore of great importance that the selection and application of materials be based on tests which evaluate operating conditions in so far as possible in the laboratory. This problem has been recognized for some time and numerous approaches have been studied. It has been our observation that a test specimen which is suitable for one particular variety of apparatus may not be equally suitable for another. Therefore, we select the variety of insulation composite sample for studying the particular insulation performance characteristics.

It is highly desirable that the user and the manufacturer of electric apparatus see eye to eye with respect to the testing of insulating materials as a basis for their application to electric apparatus.

K. N. Mathes: We agree with Moses that a test specimen which is suitable for one particular variety of apparatus may not be equally suitable for another. However, every effort is made to develop samples which have as broad an application as possible.

This often can be accomplished by keeping in mind the fundamental factors involved without attempting to duplicate the geometry of a particular application.

We appreciate Moses' emphasis on the desirability of the approach described in our work.

Magnetic Amplifiers for Naval Shipboard Applications

L. W. BUECHLER
MEMBER AIEE

ONLY the most reliable of equipment can be tolerated in a Naval vessel's electric system. Since the ship's gun controls, radar, and communication are all dependent on the ship's electric system the only thing a ship can do in case of failure of this system is retreat. It certainly could not take any active part in fighting action, in fact, a crippled ship often requires protective assistance from other ships, just when the other ships could be used most effectively elsewhere in the battle.

Keeping the ship's propulsion system operable is of prime importance if the ship is to survive. If it fails the ship becomes dead in the water and is easy prey for an enemy's guns, torpedoes, or bombs. Another very important system is the steering. Should the steering system fail the ship must stop, or run uncontrolled, usually in circles. Although great effort is devoted to making a ship's propulsion and steering not totally dependent on the electric system, often even these important systems are dependent on the ship's electric system. All large naval vessels, such as troop transports, cargo vessels, as well as combatant ships, have certain weapons, such as antiaircraft guns, which must be kept in operation, and all vessels have communication systems which are essential to their efficient operation. One of the most important of all special considerations in the design of reliable shipboard electric equipment is that of shockproofness. The mechanical shock (that is, sudden violent movement of the ship's hull and internal equipment) caused by the firing of a ship's own guns and the exploding of enemy rockets, shells, mines, and torpedoes, frequently causes extensive damage to many types of equipment.

Vacuum tubes always have been classified as a very undesirable component in a system as important as the ship's electric system. Great strides have been made in improving the ruggedness of vacuum tubes but, notwithstanding these improvements, vacuum tubes still fail too often. Contractors supplying the electric equipment often have found it difficult to accomplish various functions in equipment without using vacuum tubes. For example, in a recently developed automatic steering control, four amplifiers were required. To improve the reliability of the system, a spare set of vacuum tube amplifiers with changeover switches was provided. Frequently a loss of accuracy or performance of an item, such as a voltage regulator, has had to be permitted in order to avoid the use of vacuum tubes.

Advantages of Magnetic Amplifiers

It was late in the last war that it became evident that magnetic amplifiers could be used to good advantage in many places where vacuum tubes were previously thought to be necessary. The vacuum tube may be considered as a variable resistance in a d-c circuit; whereas, the magnetic amplifier may be considered as a variable impedance in an a-c circuit. In either case a small amount of control power is used to vary the current or power in the power circuit. Magnetic amplifiers consist basically of saturable reactors and dry-disk rectifiers and can readily be made much more rugged and reliable than vacuum tubes. They already have been used in some applications and have been found to be very reliable and maintenance-free. It is desired and believed obtainable to have units which, once installed, will not require any routine service or maintenance during a service life of at least five years.

In addition to being very rugged and maintenance-free, magnetic amplifiers are considered to offer the following advantages:

1. They can operate from the ship's a-c supply and, for most applications, require no power supply such as the "B" supply required for vacuum tubes. Although the reactors used in the magnetic amplifier may weigh more than a comparable vacuum tube, the size and weight of a complete magnetic amplifier can be made equal to or less than the vacuum tube amplifier since the "B" power supply required with the vacuum tube amplifier is usually a large portion of the total size and weight.

2. They require no warm-up time. Components, such as gun controls, would not have to be kept continuously energized just in case they suddenly might be required.

3. They do not have the power limitations of vacuum tubes. Due to the heat loss in vacuum tubes the power output, without special cooling of the tubes and chassis, is often a limiting feature in designs. The greatest heat loss problem in magnetic amplifiers is in the rectifier. Present work indicates that rectifier efficiencies of 85 to 90 per cent are possible; the heat loss for 1- to 2-kw of output is not serious.

4. Very high power amplification per stage is possible. A power gain, that is ratio of controlled power in load to power in control circuit, of 1,000,000 to 1 or even 100,000,000 to 1 per stage is possible but not considered practical for most applications due to slow response which may range from one to five seconds. For most applications in which a response of 1/200th to 1/10th of a second is desired, a power gain of 1,000 to 1 to 10,000 to 1 per stage is considered practical. An input control signal of from one milliwatt to a few microwatts is considered sufficient to control the first stage of amplification. Smaller control signals have been used but are not considered developed to the stage where they can be used generally.

5. The time of response can be made to meet most requirements. The time of response usually is measured in cycles of time referred to the a-c power supply. For

power gains of 1,000 to 1 to 5,000 to 1 the time of response probably will be in the order of two to five cycles. This, of course, is dependent on the magnetic material and the circuits used. For 60-cycle power the time of response will run from 1/10th to 1/30th of a second. If faster response is desired, 400-cycle power (which is becoming more available aboard naval vessels) can be used and the time of response cut to about 1/200th of a second. Special higher frequency power supplies can be used if much faster response is required, such as for an audio amplifier.

Problems in Magnetic Amplifiers

It is not intended to imply that magnetic amplifiers are new. They have been known and applied for many years, beginning in about 1915. Reference 1 lists some 213 articles and patents on magnetic amplifiers and allied subjects. Several companies over the past years have used this type of amplifier in limited quantities for certain naval applications, mainly voltage regulators. In such application, the magnetic amplifier usually was developed or designed around a particular piece of equipment, and no great effort was made to develop magnetic amplifiers for general use as a possible substitute in certain applications for vacuum tubes. Reports from Germany indicated that that country had taken a much broader interest in magnetic amplifiers. This may have been due to the limited number and variety of vacuum tubes available, but they did develop and use magnetic amplifiers for applications in which we would have used vacuum tubes. Developments have taken place over the last five years which are believed to make magnetic amplifiers more promising today than they were 15 or 20 years ago. Better magnetic steels have been developed and are being made available commercially. Better rectifiers of the germanium crystal and selenium types are now available and being further improved.

A brief discussion of the simple form of a magnetic amplifier will assist in understanding how these better steels and rectifiers can improve magnetic amplifier characteristics. Figure 1 illustrates a circuit which may be used. Assuming certain idealized conditions such as perfect rectifiers, a high impedance control winding, and an idealized saturation curve, the operation can be explained as follows. During one half cycle one reactor core, core *1* in Figure 1, is inactive; the rectifier is holding back (or absorbing) the voltage which may exist between *A* and *B*. The state of saturation in core *1* is determined by the current and turns in the control winding. During the following half cycle the rectifier associated with the winding for core *1* conducts and this winding will absorb voltage until core *1* saturates. If it saturates during this half cycle the portion of the voltage occurring after saturation appears across the load. The action on core *2* is similar but on the alternate half cycle. The voltage appearing across the load is alternating and of a shape somewhat similar to that which would be encountered with a grid-controlled thyratron tube in place of reactor core and rectifier.

Assuming the saturation curve has the shape shown by the solid line in Figure 2, the maximum voltage which can be absorbed across the power winding core *1* during its conducting half cycle would be caused by a flux change from the point *C* to the point *D* on the saturation curve. In order for the flux to start at point *C* there must be sufficient negative bias caused by the control current to bias the core during the nonconducting half cycle to the point *C* on the saturation curve. If a flux change of *C* to *D* is sufficient to equal the applied alternating voltage, practically no voltage will appear across the load when the cores are biased to the point *C;* and practically full voltage will appear across the load when the cores are biased to the point *D*. In actual practice, the saturation curves do not have such sharp corners; curve *3* in Figure 2 is a more typical saturation curve. The curve shown in Figure 3 represents the output curve obtained for one particular magnetic amplifier. It will be noted that approximately minus ten milliamperes is required to give negligible voltage across the load and plus ten milliamperes gives 34 volts across the 50-ohm load. The remainder of the applied 65 volts at plus ten milliamperes control current is lost primarily in resistance drop in the load winding, rectifier drop, and reactive drop in the cores due to the fact that the cores did not saturate sharply at plus ten milliamperes.

Magnetic Materials

Some features about the magnetic cores which can be noted from the foregoing are:

1. The steel should saturate at as low a magnetizing force as possible as this will require less power in the control winding. The maximum permeability alone of the

steel is not necessarily a good measure of the steel quality. Curves *1*, *2*, and *3* of Figure 2 might all have the same maximum permeability but give entirely different results when used in the magnetic amplifier. Permeability is usually an indication but not a measure of the power gain obtainable per stage.

2. The steel should have a very sharp knee on the saturation curve and the knee should occur as near maximum flux density as possible. Any additional flux after passing the knee of the curve causes induced voltages which makes it impractical to obtain anywhere near maximum voltage across the load. Very high values of magnetizing force are present on the core during the conducting half cycle. For example, with plus ten milliamperes, or 0.5 ampere-turn in the control winding of the magnetic amplifier illustrated in Figure 3, the maximum magnetizing force on the core during the conducting half cycle is about 700 ampere-turns. The saturation curve, therefore, should be flat from the knee to 700 ampere-turns.

3. The steel should have as high a flux density at saturation as possible. This permits smaller cores for the required voltage. In general the higher flux density steels, namely the silicon steels, do not have high permeability nor sharp saturation; therefore, the nickel alloy steels often are required notwithstanding their lower flux densities.

4. The steel should be consistent so that the two or more cores which make up the amplifier will be similar for best performance and so that various amplifiers made to the same specifications will have similar characteristics. Lack of consistency of magnetic materials has been the greatest problem to date in the magnetic amplifier program. A deviation of not greater than ±10 per cent in the magnetic characteristics would be considered very good. A deviation of ±20 per cent would be acceptable and much better than commercially available in the higher permeability materials.

5. The steel losses should be small. Eddy currents in the steel not only cause power loss but also cause the amplifier to have slower response. Hysteresis losses in addition to causing power losses may have the undesirable effect of causing a hysteresis effect on the input-output characteristic of the amplifier, that is, the output power may be different depending on whether the control is increasing or decreasing.

Developments in the field of magnetic materials which appear to have promising applications in magnetic amplifiers are as follows (Figure 4 illustrates magnetization curves for materials discussed):

1. The grain-oriented silicon steels. These have much higher permeabilities and sharper saturation than ordinary silicon steels. They should be particularly useful in power applications where the cost per pound of steel is an important factor.

2. The magnetically heat-treated silicon steels. These steels have similar features and advantages of the grain-oriented steels with the additional feature that more freedom in the choice of core structure is available since stamped laminations can be used.

3. The 50 per cent nickel-iron alloys which are now standard items with some steel companies. These have higher maximum permeabilities than the grain-oriented or magnetically heat-treated steels but are more expensive and have lower flux density at saturation than the silicon steels; therefore, their use will tend to be limited to applications in the low and intermediate power stages.

4. The 74- to 80-per cent nickel-iron alloys which are also commercially available. These are more expensive, have lower flux density at saturation, and have a higher maximum permeability than the 50 per cent nickel-iron alloys. Although their use may be limited to low power stages, they are useful for working at lower control signal inputs than any other commercially available steel.

5. The Supermalloy magnetic material developed by the Bell Telephone Laboratories but which is not yet commercially available. This material which has the highest permeability of any present material (about 1,000,000) should, when commercially available, permit working at signal levels even lower than can now be done.

6. The Permenorm-*5000Z* type of material. This material has a rectangular hysteresis loop (see Figure 5) and was originally developed by the Germans for mechanical rectifiers. It has the very desirable characteristic of saturating sharply at a low magnetizing force (about 0.15 oersted). The Naval Ordnance Laboratory has succeeded in developing a superior heat treatment process for this material and several companies are working on the problem of producing it commercially. Since it contains about 50 per cent nickel and is more expensive than other 50 per cent nickel alloys, its use probably will be restricted to low power and intermediate power stages.

Rectifiers

High quality rectifiers are essential in magnetic amplifiers. Some features desirable in the rectifiers are:

Low Forward Resistance. This is desirable in order that the power loss and the voltage drop will be kept to a minimum.

Very Low Back Leakage. A check on the magnetic amplifier in Figure 3 will illustrate the magnitude of this problem. During the conducting half cycle with a control current of ten milliamperes (0.5 ampere-turn), the

Data from tests by Naval Ordnance Laboratory

rectifier carries a maximum peak current of about 1.0 ampere. With minus ten milliamperes of control current a large portion of the alternating voltage of 65 volts rms appears across the rectifier. A back leakage in the power circuit of 0.1 per cent would amount to a peak of about 0.001 ampere or 0.7 ampere-turn, whereas, the control ampere-turns are supposed to be only +0.5 ampere-turn. The actual effect of leakage depends on the incremental hysteresis loops, operating point on the load curve, power circuit inductance, and so forth; and usually is less than indicated by this simple calculation. The leakage increases the amount of control current required and somewhat decreases the negative bias required resulting in an over-all loss in power gain.

Very Stable Characteristics. Any change in the rectifier's operating characteristic changes the performance of the magnetic amplifier in which it is used, especially if the rectifier has or develops leakage. Special consideration to the inverse voltage rating must be given in order to obtain the most stable operating characteristics. Consideration also must be given to the effect of moisture and temperature on rectifier characteristics. It is expected that the moisture problem will be avoided by using hermetically sealed rectifiers, probably enclosing them in the same container with the cores.

Circuits

Various electric circuit arrangements are possible with magnetic amplifiers but will not be discussed since circuits are beyond the scope of this article and circuits have received considerable discussion in the literature.[1-6] The particular circuit to be used will depend to a large extent on whether single-phase or 3-phase alternating power is available, whether a-c or pulsating d-c output is desired, whether the load is resistive or inductive, and the response time constant required. The magnetic circuit is very important and must be carefully designed if full advantage of the magnetic properties of the steel is to be realized.

For larger power applications, stacked laminations using air gaps may be necessary for most economical production and a sacrifice in gain or time constant caused by an air gap in the circuit has to be permitted. For most low power amplifiers it is considered that a closed magnetic path is essential. One solution is the use of stamped ring laminations and a toroidal winding. Thin strip laminations in the form of tape wound into a circular core also has been found satisfactory and about equivalent to the stamped ring cores. This form of core is necessary in using the Permenorm-*5000Z* and other grain-oriented material.

The stamped laminations as illustrated in Figure 6 give good results when used in magnetic amplifiers. For the rectangular lamination, a split winding-bobbin is placed on the center leg and all windings placed on this leg. This arrangement has advantages over the toroidal winding using the ring lamination since it permits winding a larger number of turns resulting in economical production of higher impedance windings; it permits obtaining a better copper space factor; and the winding does not stress the magnetic core. On other types of cores, special core boxes may be required to prevent stressing the core and destroying the good magnetic properties of the core material.

Figure 5. Hysteresis loops for Permenorm-5000Z steel

Data from tests by Naval Ordnance Laboratory

Figure 6. Core shapes used in magnetic amplifiers

Time Constant

The time constant of response for the majority of magnetic amplifiers is dependent to a great extent on the inductance of the control winding. The time constant of the control winding can be controlled best by using magnetic materials and magnetic circuits which require very small amount of control power. Fewer turns and more resistance in the control winding then can be used to reduce the time constant of the build-up of current in the control winding. Somewhat the same effect can be obtained by the use of negative feedback with the additional advantage of improving the linearity of the response. Both control winding resistance and negative feedback involve sacrificing gain to reduce the time response. Since gains of many thousand or even several million per stage are obtainable, reducing the gain to shorten the time constant is not as undesirable as might at first be thought. As indicated previously time constants of two to five cycles with a power gain of 1,000 to 1 to 5,000 to 1 per stage are considered to be reasonable values.

Applications

In general, magnetic amplifiers are believed to be usable for many applications where vacuum tubes presently are required and used. They are not believed to be usable in their present form at radio frequencies due to high eddy current losses in the core. At present 0.001- to 0.002-inch thickness is about the thinnest laminations which are obtainable commercially in high permeability magnet material.

Further development and use of ferrite materials may permit magnetic amplifier work at high frequencies.

Some naval shipboard applications for which magnetic amplifiers may be used are enumerated and described briefly in the following list:

Voltage Regulators. As indicated previously, there already have been applications along this line, and it is believed that a larger use of magnetic type amplifiers will be made in future regulators.

Speed and Frequency Regulators. The amplifier can take the speed (or frequency) signal and amplify the signal to control the prime mover to the desired speed. Developments of this nature are in process.

Line-to-Line Voltage Regulators. Magnetic amplifiers already are being applied for this purpose, and, as voltage requirements become more stringent, this application will probably grow.

Automatic Battery Charger Controls. Limited applications of magnetic amplifiers in this respect already have been made and others are now under consideration.

Servo Amplifiers. This use is probably one of the broadest fields for magnetic amplifier application. Many servo systems

aboard ship require amplifiers where the response time of a magnetic amplifier would be satisfactory. The Germans thought this application was very promising and actually used magnetic type of amplifier for a number of shipboard servo systems.[4]

Instrument Amplifiers. On several occasions the need has arisen for an amplifier to take very low level signals and amplify them to the point where they can be used to operate a meter of shockproof design.

Audio Amplifiers. By using an a-c power supply of 10,000 to 20,000 cycles, magnetic amplifiers appear to hold considerable promise of producing a high power, light weight, amplifier for this application. The main problem is in generating the high frequency power supply. Motor generators appear to be the quickest solution to this problem, but other methods not employing vacuum tubes are under consideration.

Control Relays. Magnetic amplifiers can find use in some of the metering or detecting circuits and in eliminating auxiliary control circuit relays.

Other Miscellaneous Applications. Devices such as temperature regulators, time delay elements, modulators, current regulators, and so forth, also provide applications for magnetic amplifiers, although at present little developmental work is underway for these particular applications.

Developmental Program

At present, considerable effort in the form of laboratory projects and contracts, is being expended to develop the theory and design principles of magnetic amplifiers, to develop magnetic materials which best will meet the needs of the amplifiers, to develop rectifiers of suitable characteristics, and to develop the amplifiers for certain applications in which their use appears advantageous. The progress of this work has been slow and most of the results of the investigations are not presently available; therefore much of this summary has had to deal with only the general results. Several applications not mentioned herein have been made in classified equipment and cannot be discussed.

It is hoped that eventually various types and sizes of magnetic amplifiers can be made available for general use so that they will not have to be designed for each application. The application then can be designed to use the type and size which most nearly meets the requirements of the job.

The work to date has confirmed earlier beliefs that magnetic amplifiers can be used for many shipboard applications wherein previously only other devices, such as relays or vacuum tubes, were considered practical. The ability to make magnetic amplifiers very rugged and service-free is considered to be of very great value to the Navy, especially for important circuits or systems in which reliability and continuity of service are of prime importance.

Discussion

H. F. Storm (General Electric Company, Schenectady, N. Y.): The following is intended to augment Buechler's excellent paper by providing some numerical data on the actual performance of an alternator equipped with magnetic amplifiers for voltage control and also for static excitation. The continuous rating of the synchronous 3-phase alternator is 278 kva, 220 volts: power factor 0.8 inductive; the 1-minute rating is 415 kva, power factor 0.5 inductive; frequency 420 cycles, 28 poles, open circuit field time constant 0.25 second; all a-c power for regulation and excitation is obtained from the alternator itself.

Significant for the performance of the set are the following items:

1. Speed of re-establishment of steady-state alternator voltage after a load change.
2. Steady-state alternator voltage as function of load.
3. Alternator current during short circuit.

The speed of response according to item 1 was tested by suddenly applying a 2 per unit load at a power factor of 0.4 inductive. Figure 1 of the discussion shows the alternator voltage and the field current during this disturbance. The alternator voltage very quickly re-establishes itself. Except for the first dip, which is unavoidable, the deviations from the steady-state voltage become too small for accurate numerical evaluation. In order to accentuate these deviations, an especially designed circuit was used which amplified these deviations by suppressing the zero line. The result is seen in Figure 2 of the discussion. Within a period of 310 milliseconds after application of the load, the alternator voltage is within ±1 per cent of

Figure 1. Transient response of 415-kva generator (3-phase 420-cycle) equipped with magnetic amplifier-type regulator, application of 2 per unit load

Figure 2. Transient response of 415-kva generator (3-phase 420-cycle) equipped with magnetic amplifier-type regulator, application of 2 per unit load

Figure 3. Transient response of 415-kv generator (3-phase 420-cycle) equipped with magnetic amplifier-type regulator, application of 2 per unit load

Figure 4. 415-kva generator (3-phase 420-cycle) under near short circuit conditions. Generator equipped with magnetic amplifier-type regulator

its finally sustained value. By suddenly removing the same load (Figure 3 of the discussion), the alternator voltage establishes itself in 130 milliseconds within ±1 per cent of the finally sustained voltage. The change of steady-state voltage between "on" and "off" is 0.45 per cent for the foregoing loading.

For rated loading, the change in steady-state generator voltage is 0.18 per cent between no load and rated, continuous load.

For reasons of selective circuit breaker tripping, it is sometimes desirable to obtain a sustained current of 2.5 to 4 per unit during short circuits. Figure 4 of the discussion shows an oscillogram of a short-circuit test in which a sustained short circuit of 4 per unit is obtained. At the point of measurement, the alternator voltage did not quite reach zero because of impedance in the cables to the short-circuiting breaker. This residual alternator voltage, however, is only coincidental and has no bearing on the performance of the system.

Proposed Circuit for Aircraft Reverse-Current Cutout

J. M. MARZOLF
ASSOCIATE AIEE

An investigation was undertaken to find a means of improving the performance of aircraft reverse-current cutouts under the extremely wide variations in operating conditions encountered in aircraft. The function of the reverse-current cutout is to connect its associated generator to the main bus when conditions are such that the generator is capable of delivering power to the bus and to disconnect the generator when the bus supplies power to the generator. Due to the wide variations in operating conditions encountered in aircraft, and the strict specifications imposed on its operation, it has been extremely difficult to obtain a completely satisfactory cutout.

Specifications for Ideal Aircraft Cutout

An ideal cutout designed for use on present aircraft should operate satisfactorily on any voltage between 20 and 30 volts, independently of the voltage regulator. It should close the main contactor to connect its associated generator to the bus when the generator voltage is 0.2 volt higher than the bus voltage, and should reopen it if a reverse current, equal in magnitude to five per cent of the generator full-load current, flows through the generator. Its operation must not be affected by wide variations in ambient temperature (−55 degrees centigrade to +70 degrees centigrade). It should not be affected by severe conditions of shock and vibration, dust and humidity, or altitude. It should compare favorably with existing cutouts in size and weight, and should be simple and dependable in operation. It should not provide a drain on the batteries when the generator is inoperative, and the pilot relay preferably should be universal in design so that the same pilot relay might be used on any generator, regardless of its current rating. Its power consumption should be limited to a reasonable value.

It was decided early in the investigation that the only satisfactory type of cutout was one which employed the differential voltage between generator and battery as the controlling factor. Thus, the differential voltage coil (or other controlling element) must operate on 0.2 volt in the forward direction, but must be able to stand at least 10 volts continuously in the reverse direction. (This is based on the assumption that a polarized auxiliary relay is used in the differential coil circuit which will not close until the generator voltage builds up to approximately 20 volts in the proper direction. If this is not done, the differential coil circuit must be designed to withstand 30 volts under normal conditions and 60 volts if the generator builds up in the reverse direction.) Even with this auxiliary relay, however, there is a ratio of full-load voltage to operating voltage for this device of 50 to 1 on the differential coil, making the use of a larger wire size necessary and, consequently, increasing the weight and size tremendously. Similarly, the coil (or other element), to control the opening of the cutout under reverse current, must have a ratio of full-load voltage to operating voltage of 20 to 1 (without allowing for generator overload). Thus, a coil operating under these conditions must either develop a very small operating signal or else be impractical due to size and weight limitations. The insertion of an ideal rectifier or current-limiter in the circuit would reduce these ratios to reasonable values. However, there is no known rectifier having a stable temperature characteristic which will pass appreciable current with 0.2 volt across its terminals and no suitable current-limiter has been found.

Construction of Proposed Cutout

In the course of the investigation many different ideas were investigated, the most promising of which is embodied in the circuit diagram of Figure 1. It consists, essentially of two units:

1. The main contactor with auxiliary contacts comprising a triple-pole double-throw switch.
2. The control element.

The control element consists of:

(*a*) A small balanced permanent magnet mounted on pivots and free to rotate between two contacts without restraining springs of any kind and actuated by three coils (differential, reverse, and residual), all wound on the same magnetic core between whose poles the permanent magnet is free to rotate. This element is schematically represented in Figure 2.

(*b*) A *2D21* thyratron tube and associated current regulator for its heater.

(*c*) A pilot relay having an operating coil, a holding coil, and a safety coil.

(*d*) A small insensitive polarized auxiliary relay in the differential coil circuit.

Components 1 and 2 do not need to be located in physical proximity with each other, but can be located according to convenience and connected by a suitable cable.

Method of Operation of Proposed Cutout

To explain its operation, reference is made to the circuit diagram given in Figure 1. Assume that the main contactor is open and the generator voltage is zero. In this condition, since the polarized auxiliary relay in the differential coil circuit is open, there is no connection either across the battery or between the generator and battery, and no stand-by

Paper 48-223, recommended by the AIEE air transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 21, 1948; made available for printing August 24, 1948.

J. M. Marzolf is with the Naval Research Laboratory, Washington, D. C.

power is consumed. The triple-pole double-throw switch is in the upper position as shown, and the permanent magnet control element is also in the upper position. When the generator voltage increases to approximately 20 volts in the proper direction, the polarized auxiliary relay in the differential coil circuit closes, thus making the cutout operative. This relay should be polarized to prevent burning out the differential coil if the generator voltage builds up in the wrong direction and could be accomplished very simply by use of a series rectifier in its operating coil circuit. Since the battery voltage, however, is still higher than the generator voltage, current will flow through the differential coil in the reverse direction, and hold the permanent magnet in the original position, and the cutout will not close. As the generator voltage rises, it reaches a value 0.2 volt higher than the battery voltage, at which time the flux from the differential coil is sufficient to overcome the residual flux in the magnetic core between whose poles the permanent magnet armature is mounted. This causes the permanent magnet to rotate and make instantaneous closure with the lower contact, impressing the full positive voltage on the grid of the thyratron tube through a suitable limiting resistor, and causing the tube to fire continuously regardless of subsequent grid voltage. This contact does not need to be continuous to cause the tube to fire; therefore, no contact springs are required on the permanent magnet armature and the mechanical force developed between the permanent magnet and the operating coil can be very small. The plate current of the thyratron tube passing through the operating coil of the pilot relay causes it to close. This causes the main contactor to close and at the same time the pilot relay is locked in by its holding coil. When the main contactor closes, it mechanically throws the auxiliary contacts which comprise the triple-pole double-throw switch to the lower position as shown and, in passing from one position to the other, instantaneously opens the plate circuit of the thyratron tube extinguishing it, but the pilot relay and main contactor remain closed. The permanent magnet is now in the lower position and is held there by the action of:

1. The reverse coil (as long as the normal load current flows in the main circuit from the generator to the battery).

2. The residual magnetism of the magnetic core of the control element, thus insuring that the thyratron tube will not fire again.

Assume that conditions in the main load circuit now change so that the generator voltage is less than the battery voltage, causing reverse-current to flow from the battery to the generator. This causes a voltage drop across the generator series field which is proportional in magnitude and direction to the load current. This voltage is impressed on the reverse coil and, at its operating point, is sufficient to overcome the residual magnetism of the magnetic core controlling the permanent magnet control element. This causes the magnet to rotate to the upper position and impresses a positive voltage on the grid of the thyratron again causing it to fire. This time, however, the current passes through the operating coil of the pilot relay in the opposite direction and overcomes the holding coil, allowing the pilot relay and main contactor to open. The current through the operating coil of the pilot relay is limited by a suitable resistor to preclude the possibility of the pilot relay being closed accidentally by current in this direction. In other words, the current through the operating coil is just sufficient to overcome the holding coil but not sufficient to close the pilot relay from the open position. As the main contactor opens, it mechanically returns the triple-pole double-throw switch to the upper position and, in so doing, interrupts the thyratron current long enough for the tube to be extinguished and the cycle can be repeated.

The purpose of the residual coil is to restore the residual flux in the magnetic core of the permanent magnet control element and thus insure uniform operation of the control element, regardless of the magnetic history of the core. The residual coil is connected in the plate circuit of the thyratron tube and its design is not critical but should be sufficient to carry the flux density of the magnetic core well above saturation for the lowest value of residual coil current that will be encountered (with the operating coil of the pilot relay, the residual coil and the limiting resistor for the reverse-current operation all included in the plate circuit of the thyratron tube and for minimum plate voltage). By insuring that the flux density in the core exceeds its saturation value on each operation of the cutout, the magnetic core will follow substantially the same hysteresis loop and the cutout will operate at the same point each time. In addition, a high value of residual flux is guaranteed to prevent spurious operation under conditions of shock or vibration at no load condition.

It will be necessary to include a ballast lamp in series with the heater of the thyratron tube in order to insure operation of the tube, without injury, under the wide variations of terminal voltage encountered. This ballast lamp will not affect the operation of the cutout but is inserted only as a protective device to prevent burning out the thyratron tube heater under the extremely wide variations in voltage that must be tolerated.

A third coil, designated as a "safety coil," should be wound on the pilot relay and connected in series with a suitable rectifier across the generator series field and designed to open the pilot relay under very large reverse-currents in the main circuit. This coil should be designed to operate the pilot relay at such a high value of reverse-current that, normally, it will not operate the cutout. It is merely included as a safety feature to insure that the cutout will open even though the thyratron tube were to burn out while the main contactor was closed. It would insure that the cutout "fail-safe." The coil should be designed with a suitably large time constant so that the pilot relay will have sufficient time to open, regardless of the steepness of the reverse-current surge characteristic, before the safety coil current reaches a value sufficiently high to hold the relay closed by current in the reverse direction. Thus, the pilot relay should open, mechanically, very rapidly and the current in the safety coil should

Figure 1. Circuit diagram for proposed reverse-current cutout

Figure 2 (left) Schematic representation of magnetic circuit of control element for proposed reverse-current cutout
Figure 3. Experimental model of proposed reverse-current cutout

rise relatively slowly regardless of the surge voltage applied across its terminals. If these two factors are properly taken into consideration in the design of the pilot relay, the pilot relay will never remain "locked" closed by the safety coil current regardless of the steepness of the reverse-current surge.

Factors to Be Considered in Design

In the design of the cutout, certain points should be kept in mind. The control element should be hermetically sealed to prevent interference by dust and moisture and prevent "adjustment" by poorly trained technicians. If sealed in a dry atmosphere, it would prevent interference by frost or ice on the operation of the control element. If the cover were made of iron or steel, it would serve also as a magnetic shield to prevent interference by any stray fields that might be present. The permanent magnet should be balanced and mounted so that vibration, shock, position, or physical changes in dimensions due to extremes of temperature would not affect its operation. It should also be as small and light as practical, in order to be quick acting, and its bearings should be as frictionless as possible. Should future investigations indicate that this cutout is too responsive to transients on the system, the speed of response can be decreased easily by placing a short-circuited copper slug around the magnetic core of the control element. The core material for the control element, should have a relatively high residual magnetism to insure stability under generator no-load conditions by developing sufficient force to hold the permanent magnet stationary under all conditions of shock and vibration, and should also have a low coercive force so that a small applied signal, of the proper polarity, will operate the cutout. It is suggested that possibly use of some of the newer magnetic materials having square hysteresis loops might be advantageous. The permanent magnet in the control element should be constructed of a material having a high coercive force and should be made as light and small as possible.

Advantages of Proposed Cutout

A cutout based on this principle would be practically independent of temperature, altitude, and terminal voltage (from 20 to 30 volts) and, since it operates on a very small number of ampere-turns, the differential and reverse-current coils can be designed for a 5,000 and 2,000 per cent overload respectively, and still be relatively small in size, thus overcoming the problem outlined before. Also, since the voltage drop across the series fields of all aircraft 28-volt d-c generators is approximately the same at full load, regardless of power rating, for the equalizer connection to the voltage regulator, the same cutout could be used on any system regardless of generator rating. Furthermore, the components may be located remotely for convenience, accessibility, and so forth, it merely being necessary to connect the contactor and control element by means of a suitable cable. It would lend itself also to an installation wherein the control element is made in a hermetically-sealed plug-in type unit which could be removed and a new one installed quickly in case of failure. The cutout can be made small and light since it operates on a pulse technique and thus, the operating coil on the pilot relay, the residual coil on the control element and the thyratron tube can be overloaded instantaneously. Furthermore, the holding coil on the pilot relay, although designed for continuous operation, operates only when the relay is closed under conditions of zero air gap and would thus be smaller than the conventional relay coil. The power loss in the cutout would be low since no additional shunts or other devices are required in the power circuit, and the only appreciable power input to the cutout would be that to the heater of the thyratron tube. Since there are no springs or mechanical restraining torques on the control element and no contact springs (instantaneous contact only needed), it can be made quick-acting and the permanent magnet will never be subjected to surges in the reverse direction that might reverse its polarity accidentally. Provided the surge did not build up faster than the permanent magnet could move, the magnet would never be subjected to a reverse polarity, since it always lines up mechanically with the existing field. If the control element magnet is made sufficiently light and friction-free, this reverse polarity would not be a problem since, the faster the surge increased, the greater the mechanical force and the quicker the element would move.

Experimental Results

An experimental model was constructed and tested to demonstrate the soundness of the principles involved. A general view of this model is given in Figure 3 which shows both components connected by a suitable cable. There was no attempt made in this model to keep the size and weight factors to a minimum. It performed entirely satisfactorily and as predicted under the variations of voltage for which it was designed. However, since no attempt was made in the mechanical design to take care of the factors of vibration, shock, hermetic sealing, variations in position, changes in physical dimensions due to temperature variations, and so forth, no tests were actually performed under operating conditions. These should suitably be postponed until the necessary developmental engineering could be accomplished. Sufficient trials were made, however, to convince the author that the principles involved are sound and that a properly designed cutout based on these principles would be entirely satisfactory under the extremely wide variations of conditions encountered by this device under operating conditions.

No Discussion

A Polarized Relay as an Aircraft Control Element

ROYCE E. JOHNSON
FELLOW AIEE

FRANK A. GLASSOW
ASSOCIATE AIEE

DEMAND for simple, lightweight, reliable control equipment for automatic controls in aircraft has resulted in the development of a sensitive polarized relay having such a variety of applications that its characteristics are of general interest. In this relay a permanent magnetic field is combined with that of the relay coil in a manner to produce great sensitivity without the loss of stability and inherent strength. These characteristics have been found most useful in mobile equipment where direct current is the primary source of electric power and where control devices must be held to a minimum in size and weight.

To be suitable for use in aircraft controls, a polarized relay must embody the extraordinary features of design dictated by the severe environmental conditions it will encounter. Not enough emphasis can be placed on the necessity for rugged design, simplicity, and ease in servicing control devices. In determining the qualifications of a polarized relay as an aircraft control element, it is analyzed in regard to the following characteristics:

1. *Sensitivity.* Sensitivity should be adequate for the control function, but it should not be stressed at the expense of stability.

2. *Speed of Response.* Operating times for contact closure and release should be low. Under three milliseconds is desirable for high-speed control.

3. *A-C Sensitivity.* Response of the relay to various frequencies is an important factor in some applications.

4. *Vibration.* The effect of vibration warrants detailed study and it may require countermeasures to minimize adverse performance.

5. *Over-Voltage.* Although only a few millivolts may operate the polarized relay, the effect of excessive voltage applied to the coil should be considered.

6. *Stray Field Sensitivity.* Careful consideration should be given to stray fields which may affect a sensitive polarized relay.

7. *Arc Suppression.* To insure long-troublefree operation, arc suppression is usually recommended. Correct suppressor values are dependent on load and type of contact material.

8. *Contacts.* The most desirable contact material ordinarily depends on load and ambient conditions. Extensive experimentation yields the most accurate criteria.

This analysis of characteristics is applied to the polarized relay described in this paper, and technical data appear in the form of graphs and oscillograms. Current uses of this relay may be classified as

1. Remote Positioning—cowl flaps, landing flaps, trim tabs, valves, dampers, nose wheels, cameras, gun sights.

2. Synchronization—landing flaps, trim tabs, flap-stabilizer.

3. Temperature Control—gasoline or electric heater cycling, cockpits and cabins, carburetor air, engines, wing and empennage surfaces, windshields, camera compartments.

Typical examples of the basic applications are described in detail in order to illustrate the basic principles involved. The examples serve also to point out the relative simplicity of control circuits using polarized relays and the few precautions that promote reliability.

Description of Relay

The basic principle of the relay is essentially that of a magnetic bridge similar to the one shown schematically in Figure 1. Symmetrical pole pieces cause the magnetic flux to pass through two identical air gaps while an armature extends between the midpoints of these two air gaps, dividing each gap into two sections or arms of the magnetic bridge. The armature in this magnetic circuit corresponds to the galvanometer in a Wheatstone bridge circuit, in that any magnetic potential difference between the centers of the magnetic gaps causes a flux to pass through the armature. It follows that if there is flux through the armature the flux densities in adjacent magnetic arms are different and therefore there will be a net transverse force at each end of the armature.

Flux from the relay coil, as is evident in the figure, must pass through the armature. In so doing, it increases the flux in one pair of diagonally-opposite magnetic bridge arms and decreases the flux in the other pair. The resultant unbalance in magnetic forces rotates the armature against the torsional spring restoring force.

Mathematically the magnetically produced torque on the armature, while it is in the central position, may be stated qualitatively as

$$T \propto \Phi_M \Phi_C$$

where T is the torque,

Φ_M is the main flux from one pole tip to its mating tip

Φ_C is the flux set up by the relay operating current

After the armature deflects slightly this torque is augmented by an additional torque produced by a slight redistribution of, and increase in, the main

Figure 3. Representative operating and release time curves (215-ohm 2,950-turn coil)

flux, part of which is diverted through the armature by the shortening of the gaps to poles of opposite polarity at either end of the armature.

Bisymmetrical construction of the relay, which is made possible by the magnetic bridge principle, facilitates accuracy in production and provides inherently good balance for the armature. Two parallel Alnico magnets, one at either end of the relay as shown in Figure 2, energize the pair of low retentivity pole pieces which serve as yokes to hold not only the magnets but also the armature subassembly and the stationary contacts.

The armature subassembly shown in Figure 2 is held by clamping the ends of the side rails between the pole pieces. These side rails are an integral part of the beryllium copper punching which contains also the torsional arms and contact fingers. This punching, after being formed and heat treated, has a Nicaloi armature riveted to it.

Dual purpose magnetic shunts provide means for accurately adjusting the sensitivity and, within a limited range, for centering the armature with respect to the poles. Four symmetrically located shunts have been found desirable.

Stationary contacts of this single-pole double-throw relay are carried on brackets mounted on the lower pole piece. Insulated studs permit the stationary contact screws to be adjusted accurately.

Three-point mounting of the relay structure on the phenolic base eliminates the decalibrating effect of mechanical strains set up in the base when it is stressed. Phenolic bases for mounting directly on a panel or with integral vacuum-tube type octal bases are standard.

Figure 2. Relay and armature subassembly (Patent number 2,443,784 and patents pending)

Characteristics

Sensitivity. An input of 40 microwatts (1.3 ampere turns) as the operating or sensitivity power of the single coil polarized relay has been the minimum for production quantities. However, an excitation of 1.9 ampere turns or more provides better stability and facilitates calibration. Multiple coil relays have the same ampere turn requirements.

The release voltage is less than the operate voltage by an amount which varies somewhat with the sensitivity of the relay, the retentivity of the high permeability armature and pole pieces, and the amount of voltage applied in excess of the minimum operating voltage. For voltages up to 10 times sensitivity voltage the release voltage ranges from about 5 to 65 per cent below the operating voltage.

Operating Speed. The relatively low mass of the armature and the stiffness of the torsional spring permit rapid response of the relay. Data for closing and opening times for several voltage and series resistance combinations with a typical relay are shown in Figure 3.

Typical oscillograms showing the interval between the application of a square wave voltage and the closing of the con-

tact are shown in Figure 4. These oscillograms were taken on a cathode-ray oscilloscope using a 1,000-cycle timing wave on one pair of plates and a voltage across the capacitor in an R-C circuit on the other pair of plates. The relay and R-C circuit were energized simultaneously spreading the 1,000-cycle timing wave across the fluorescent screen. An auxiliary voltage was superimposed on the 1,000-cycle timing signal by the operation of the polarized relay contact, making it possible to determine the time delay by counting the number of cycles before the contact closed.

One or two short contact bounces of less than 1 millisecond duration were observed for operating voltages between 1.5 and 4 times sensitivity voltage. The duration of these bounces is so much shorter than the operate and release times of the d-c relays ordinarily used as secondary relays[1] that chatter of the secondary relays would not be expected from this bouncing. To the knowledge of the authors, no difficulty has resulted from this bouncing. The effect of this bounce can be largely eliminated, if necessary, by the use of an arc suppressor having adequate capacitance. However, actual usage conditions are generally different than for these oscillograms in that the voltage on the relay coil changes gradually in most applications rather than by large increments. Gradual application of voltage to the coil does not cause contact bounce.

Frequency Response. Figure 5 indicates the range of frequency to which the relay will respond. Conditions approaching resonance exist in the vicinity of 90 and 190 cycles per second. The smaller irregularities in the curves appear to be related to harmonic vibrations in the armature subassembly.

Equivalent Inductance. Calculations of equivalent inductance, where the effects of armature inertia, spring constant, and magnetic reaction on the coil are considered as part of the coil inductance, yield values between 1 and 2.8 henries for "make" operations of the relay for the conditions of Figure 3. The equivalent inductance is for a circuit in which the current reaches the magnitude of the sensitivity current of the relay in the same time interval as measured for the contact to close.

Under contact opening conditions the equivalent inductance varies over a much wider range, being between 9 and 6 henries for excitations ranging from 105 to 125 per cent of sensitivity, and decreasing to about 1 henry for 600 per cent of sensitivity excitation. This greater variation is to be expected for opening operation because excitation with current in excess of sensitivity current causes energy to be mechanically stored in the contact finger which yields slightly as a spring when torque is exerted by the armature. Conversion of the potential energy to kinetic energy in the armature upon de-energization of the relay affects its speed and also the armature reaction voltage induced in the coil.

Inductance calculations based on alternating current and voltage measurements with barely enough input to close the contacts indicate an inductance of about 4.5 henries between 20 and 70 cycles, decreasing to practically zero at about 90 cycles and again at 190 cycles. When excited sufficiently to vibrate the armature slightly but not close the contacts, the impedance of the relay is inductive below the lower resonant frequency and above the higher resonant frequency. Between the two resonant frequencies the reactance is capacitive. The effects produced by limiting the armature travel, as the contacts do, cause considerable variation in the impedance as the input is increased above the amount which barely closes the contacts.

Vibration Sensitivity. Although the armature construction is such that it is very well balanced, it will be affected by rotational acceleration in a plane perpendicular to its torsional axis. When mounted so that linear acceleration is parallel to the long dimension of the armature the effects of vibration are somewhat more noticeable than for other directions of acceleration. Vibration parallel to the torsional supports is least noticeable.

The use of secondary relays with slugs or a short-circuited coil, or a resistor in parallel with the secondary relay coil, aids in eliminating chatter of the secondary relay contacts when the polarized relay is subjected to vibration. A resistance-capacitance arc suppressor on the polarized relay contacts is also of appreciable value in overcoming the chatter producing effects of vibration. Curves showing the range of polarized relay voltages which will permit chattering of the secondary relay when both relays are subjected to a range of vibration frequencies are shown in Figure 6.

In many cases the most satisfactory method of preventing contact chatter either in the polarized relay or the secondary relay is that of electromagnetic detenting. Two auxiliary detenting coils are wound over the main coil of the polarized relay, one in series with each contact,

Figure 4. Oscillograms of contact operation (215-ohm 2,950-turn relay—1,000 cycle timing wave)

Operation	Coil Voltage	Circuit Resistance, Ohms
(A) Make	0.60	226
(B) Make	0.16	334
(C) Break	1.37	220
(D) Break	0.34	1,100

so that when either contact closes the load current sharply augments the initial excitation to develop a definite pressure on the contact. The detenting magnetomotive force generally is between 10 and 25 per cent of the sensitivity magnetomotive force. Consequently, when detenting is used the polarized relay contacts open at 10 to 25 per cent less voltage than would otherwise be the case. Detenting also permits the contacts to open more rapidly at "break."

Over-Voltage. Considerable excess voltage can be applied to the relay coil without damaging the relay. For example, a 215-ohm relay having a sensitivity of 0.15 volt (0.001 watt), had its control point shifted slightly by retentivity of the pole pieces when subjected to 25 volts. The shift was removed by passing a reverse current through the coil as occurs in normal operation. A one second application of 220 volts of direct current to an 88-ohm 1,900-turn coil produced a temperature rise of 55 degrees centigrade and permanently affected the calibration. Application of 220 volts to a 215-ohm 2,950-turn coil affected the calibration but not

to such an extent that demagnetization of the pole pieces and the readjustment of the magnetic shunts could not restore its calibration.

Continuous input of $2^1/_2$ watts (23 volts on a 215-ohm coil), uniformly divided among the operating coils if more than one exists, will not cause excessive heating or damage to the relay.

Magnetic Field Sensitivity. Stray fields have some effect upon the operation of the unshielded polarized relay. Thirty-five ampere turn excitation in a 4-inch diameter coil outside the relay but concentric with its coil closed a contact on a relay adjusted for 1.5 ampere turn sensitivity. Between 70 and 90 amperes in a straight conductor across the top of the relay cover or under the base of the relay, in a plane perpendicular to the relay coil axis, also closed the contact.

Stray field from adjacent conductors or secondary relays controlled by the polarized relay may frequently be turned to good use by positioning the polarized relay with respect to the source of stray field so that a satisfactory degree of detenting will exist.

Arc Suppression. For a 28-volt series motor load (1.5 ampere stall current), a suppressor consisting of a 33-ohm resistor in series with a 5-microfarad capacitor was effective when connected across the contacts. For relay loads a higher value of resistance is necessary for best results and the capacitance should be less. Upon opening of the contacts the inductive impulse of a secondary relay charges the arc suppressor capacitor. Should the polarized relay contacts close shortly after opening, as a result of vibration, for example, while the arc suppressor capacitor is still charged to a high voltage, the discharge current will be excessive if not limited by adequate resistance, causing welding of the contacts. Obviously when the capacitor is small it will be charged to a higher voltage than a large capacitor, and consequently, the peak of the transient discharge current will be greater if discharge occurs at peak voltage.

Resistors in parallel with the coils of secondary relays have, in some cases, been found more effective in avoiding contact welding than conventional R-C suppressors. A typical value of resistance is 470 ohms in parallel with a 750-ohm 10-to-13 henry relay. However, it has been observed that with only the parallel resistor there is tendency for pin point buildup on the negative contacts. This negative contact pin point apparently results from the cold emission which takes place when the contact gap is less than 0.0003 inch.[3]

A combination of a resistor in parallel with the coil of the secondary relay and an R-C suppressor across the contacts of the polarized relay has five desirable features.

1. The shunt resistor absorbs part of the coil energy when the contacts are opened, thereby reducing arcing.
2. The rate of opening for the secondary relay is appreciably decreased, minimizing effects of vibration.
3. Physical size of the capacitor is reduced.
4. Capacity and the resultant energy discharged through the contacts at make are less than when no shunt resistor is used.
5. The constants can be adjusted to prevent the pin point formation on the negative contact.

A half-wave selenium disk rectifier in parallel with the coil of the secondary relay to absorb the transient when the polarized relay contacts open has been found unsatisfactory for preventing contact welding. Upon first thought it appears that the rectifier would make an ideal arc suppressor, but a study of Glen Ramsey's paper,[3] indicates that there can be a reverse current through a rectifier when it is first energized. This apparently explains the failure of the rectifier to satisfactorily prevent contact sticking.

Contacts. Because of the low contact

Figure 5 (left). Frequency response characteristics

Input barely sufficient to cyclicly close contacts. (215-ohm 2,950-turn coil, 2.05 ampere-turn sensitivity)

Figure 6. Effect of vibration on operating voltage

Contacts referred to are those of the secondary relay which was controlled by the polarized relay. Both relays were vibrated with 0.06 inch total amplitude, perpendicular to plane of armature

Table I. Typical Contact-Life Data

Nature	Lead Volts, Direct-Current	Lead Amperes	Cycles of Operation	Coil Input, Sine Wave Cycles per Minute	Coil Input, Sine Wave Ratio of Peak to Sensitivity of Volts
Resistance	30	0.5	400,000	6	1.1
Relay	30	0.04	over 3,000,000	6	1.3

* Relay tested by a user with square-wave input and germanium rectifier suppressor.

pressure and slow armature movement, particularly when the polarized relay is used as a contact-making galvanometer in resistance bridge circuits, the contact duty differs from that in conventional relays. Fine silver contacts were originally used for controlling small reversible 24-volt series motor actuators without the use of auxiliary relays and without detenting coils on the polarized relay. Motors with fixed load current rating of 1 ampere and stall current of 1.5 amperes, 28 volts, have been successfully controlled. However, under plugging conditions the contacts occasionally stuck and, if the polarized relay was used too long without proper servicing, contact material transfer would eventually cause difficulty. The trend now is to use electromagnetic detenting in conjunction with interlocked secondary relays to handle the reversing motor current.

When sulphurous atmospheric conditions exist and only small currents, less than 0.25 ampere, are to be controlled, platinum-ruthenium alloy contacts are superior to silver. The platinum-ruthenium contacts are more stable chemically than silver but will stick due to welding on lower current than will silver contacts.

Laboratory tests, using suitable arc suppression with no electromagnetic detenting, indicate that contact life is reasonably long if the contacts are not overloaded. Typical life data for silver contacts are shown in Table I.

Testing technique for the contact performance of the polarized relay is rather involved. It must simulate the operating conditions not only as to contact load but also in magnitude and rate of change of coil current. Sudden application and removal of the operating current will produce much more rapid "make" and "break" than occurs when the resistance of the temperature sensitive element of a bridge responds to temperature changes. Minute sticking can be detected only with slowly varying operating voltage. The effect which rate of voltage change has on contact life is partly indicated in Table I.

Operation counters are not satisfactory for detecting minor degrees of malfunctioning because it is necessary to record deviations from uniform "make" and "break" voltages. Present test procedures involve two different methods. One uses a motor driven potential dividing rheostat to supply the coils with slowly alternating filtered voltage of peak value slightly greater than sensitivity voltage and continuously recording the coil voltage in such a way as to indicate the voltage at which each contact "makes" and "breaks." The other method is to use an electrothermal self-cycling circuit under controlled ambient conditions, recording on a multipen operation recorder the length of the contact open and closed intervals.

Field of Application

A polarized relay with near-galvanometer sensitivity naturally suggests itself as the detecting element for control systems, particularly those using resistance bridge and other differential circuits for their sensing elements.

The relay with a single coil and a floating armature which can close either of two contacts, depending upon the direction of current through the coil, is suitable for many control systems based on bridge circuits. The addition to the relay of detenting or biasing coils often improves the performance of a polarized relay control system. Secondary or slave relays increase the power handling capacity of the polarized relay and can provide interlocking, control point shift and other features desirable in certain control systems.

Other control applications, usually not involving a bridge circuit, utilize double coil differential polarized relays. With such a relay the contacts will remain open as long as the difference between opposing magnetomotive forces is less than the operating magnetomotive force. Where the currents which are compared in the differential relay coils are large relative to the net operating current, the current carrying capacity of the coils becomes a factor. Likely applications for the 2-coil differential relay are in the plate circuits of electronic amplifiers, for directly comparing the currents through resistors, or for detecting the difference between two voltages, one of which may be constant.

Certain applications, using either the single or double coil relay, use only one pair of contacts or use both pairs of contacts with the relay adjusted for snap action with no intermediate floating position. Examples are, respectively, on-off temperature control and selective channel or circuit control.

Since most modern aircraft have 28-volt d-c electric systems and even those now using 400-cycle alternating current ordinarily include some d-c power, the d-c polarized relay finds its greatest use as an aircraft control element. The small size and weight of the device and the relative simplicity of control systems centered around it further enhance its field of application.

Typical Control Systems

As examples of the control systems which incorporate a polarized relay as the detector, several typical commercial and military aircraft systems will be described.

Positioning. Perhaps the first application of the polarized relay described in this article was the straightforward positioning of an actuator from some remote point. Actually it was the need to accomplish this control function in aircraft which led to the development of the polarized relay we are considering. A circuit illustrating remote positioning is shown in Figure 7. A bridge circuit is constructed of two potentiometers, one, the transmitting potentiometer which is manually operated, and the other the follow-up potentiometer, which is directly coupled to the output shaft of the actuator. The main coil of the polarized relay is connected between the wiper arms of the potentiometers so that when the transmitting potentiometer is moved counter-clockwise, current flows from C_1 to C_2 in the polarized relay. This causes the armature to close W to R resulting in a counterclockwise movement of the actuator. This movement continues until the follow-up potentiometer rebalances the bridge circuit causing the armature to resume a floating position which stops the actuator.

Positioning accuracies of ± 1 degree and long-trouble-free operation are possible with controls of this type provided a few simple precautions are followed. Several of these measures as applied to the circuit shown in Figure 7 are enumerated below:

1. The sensitivity and differential of the polarized relay, speed, friction, and inertia

Figure 7. Remote positioning of an actuator with a sensitive polarized relay

of the load, and characteristics of the actuator should be co-ordinated to prevent hunting.

2. The potentiometers should have good resolution and linearity to insure accuracy of positioning. Wiper arms should be equipped with Paliney number 7 or similar alloy contacts for long life and good conductance of small currents.

3. Since the relay contact load is inductive, arc suppression is necessary to protect the contacts.

4. Small detent coils consisting of one turn each are built into the polarized relay in order to eliminate contact chatter. They improve also positioning accuracy since the proper amount of detenting will cause the actuator to stop at the center of the dead band of the relay.

5. Power for the actuator is isolated from power for the bridge circuit so that I-R line drop caused by the actuator will not reduce the bridge voltage, causing an oscillatory chatter of the relay.[4]

The physical components of a remote positioning circuit are shown in Figure 8. In this figure, the transmitting rheostat and the polarized relay are housed together in an explosion-resistant case. The control station is shown with a reversible rotary actuator having a torque of 50 pounds inches, operating through 180 degrees at 1 rpm. The combined weight of the control station and the actuator is 2.8 pounds.

The use of the polarized relay for remote positioning is not confined to small actuators such as that shown in Figure 8, for the relay may also operate secondary power relays designed for carrying heavy motor loads. Successful applications in aircraft include remote positioning of cowl flaps, landing flaps, trim tabs, valves, dampers, and nose wheels. These represent only some of the more common positioning applications. Many others are in various stages of development and will be available soon to answer the increasing demand for simplified controls in aircraft.

Temperature Control. One of the best known and most widely used applications of the polarized relay is that of temperature control in aircraft. These applications have included control of temperatures in cockpits, cabins, manifolds, engines, wing and empennage surfaces, and windshields. The general method of accomplishing temperature control again involves the resistance bridge, one or more arms of which consist of temperature sensitive resistors. Both positive and negative coefficient resistors are used and they are constructed in various shapes to permit sensing temperature in the desired media in the most effective manner. Figure 9 illustrates several typical temperature-sensing elements, each designed for a specific application.[5]

In some of these control systems, a simple "on-off" type of control is sufficient. This is represented by the rapid cycling of a gasoline heater used to provide heated air to a cabin or wing duct or by the control of electric power dissipated in an electrically-heated windshield.[6]

The basic circuit of a control system used for cycling a gasoline-burning heater to maintain a prescribed cabin or cockpit temperature is shown in Figure 10. Each arm of the bridge circuit and the polarized relay coil has substantially the same resistance when balanced at normal temperature. A change in resistance in any arm which unbalances the bridge in the direction calling for heat

Figure 8. Remote positioning control assemblies

causes the polarized relay to energize the heater cycling relay which controls the heater fuel solenoid. The cabin elements are made of thermistor disks having a large negative coefficient, and being much more responsive than the heater elements, composed of fine wire with a positive coefficient, a small change in temperature at the cabin elements will cause a large change in the control point at the heater discharge. Many applications are in service where lowering the cabin temperature 1 degree Fahrenheit will increase the heater discharge temperature approximately 30 degrees. Other ratios can be provided readily.

Adjustment of the cycling rate from approximately 2 to 10 cycles per minute is accomplished with the frequency rheostat and a second set of contacts on the cycling relay. This method biases the bridge circuit to shift the control point a suitable amount. Shift in control point attributable to the drooping characteristic of the control is effectively offset by the reset element which responds to changes in ambient temperature.[7,8]

The polarized relay in a temperature-responsive bridge might be used also to operate a reversing motor which in turn operates a mixing valve. Proportioning control is accomplished by coupling a follow-up rheostat to the reversible actuator which rebalances the bridge after a given movement of the actuator. Such a control system is represented by the assemblies shown in Figure 11, which comprise a wing anti-icing control system. The circuit simply consists of a typical bridge with one thermistor sensing element suitable for riveting to the inner surface of the wing. The polarized relay operates two small secondary relays which position the proportioning actuator to

Figure 10 (left). Circuit elements for rapid cycling of an aircraft gasoline heater for cabin temperature control

satisfy the heat requirement of the wing.

The use of the polarized relay as a control element in aircraft temperature control has resulted in many simple, reliable systems which usually offer a considerable saving in weight and cost. The wide variety of resistance-type temperature-sensing elements, both positive coefficient and negative coefficient, high or low time constant, flat and thin or long and narrow, have made possible the adaptation of this control method to practically any temperature regulating problem existing in aircraft.[8] It is felt that even greater possibilities of new application exist with proper design of control systems using the polarized relay.

Advantages and Limitations

As with any unusual electrical or mechanical device, the possibility of misapplication is ever present. Almost as frequently as the many advantages of the relay described are not fully realized, the several limitations are overlooked. In order to evaluate the capabilities of the polarized relay discussed in this article, the features of the relay and its application are enumerated below:

Advantages

1. The polarized relay has extreme sensitivity, operating on as little as 40 microwatts or 1.3 ampere-turns.

2. The relay weighs only 6.5 ounces, and its size is $2^5/_{16}$ by $1^7/_8$ by $1^7/_{16}$ inches.

3. The relay is structurally strong and has withstood, without mechanical failure, severe operating shocks encountered in aircraft and missiles. No bearings are used in the armature, the only moving part of the device.

4. Coil resistances may vary from a fraction of 1 ohm to 10,000 ohms in order to match associated electric circuits.

5. Rugged contacts of either fine silver or platinum-ruthenium alloy will carry up to 1/2 ampere at 28 volts of direct current.

6. Auxiliary coils for biasing or detenting are easily added to the main coil spool.

7. Field adjustment of sensitivity is readily accomplished by means of magnetic shunts.

8. Contact closure time is extremely short.

9. The armature may be arranged either to float or to remain closed to the contact last operated, such as in a memory relay.

Limitations

1. Since contact pressures in this type of relay are not large, an arc suppression circuit usually is necessary to prevent sticking or welding of the contacts.

2. To minimize the effects of vibration when the contacts are about to close or open, detenting of the contacts by one means or another is advisable.

3. Judicious location of the relay is necessary since the presence of other electrical fields, both direct and alternating current, may shift the calibration or induce chatter. Large pieces of iron or steel near the relay may have similar effects.

4. Although Nicaloi steel is used for the armature and pole pieces of the relay, a slight polarization or hysteresis effect results from impressing high voltages on the relay coil. This is removed readily by the subsequent normal reversals of current in the coil or by the application of a small a-c voltage to the coil.

5. Sudden shock, such as that resulting from rough handling or dropping, has been known to shift calibration slightly, but differential ordinarily remains unchanged in spite of severe treatment.

Although the limitations of the relay may appear to be somewhat formidable, it has been found by experience that to overcome them in many cases actually requires no more than good application engineering.

Selective Tripping Arrangements for Protection of Ship's A-C Electric Distribution Systems

J. R. COLE
ASSOCIATE AIEE

THE NEW AIEE marine specifications just being published[1] call for the protective devices in shipboard a-c distribution systems to be arranged for selective operation so that a fault will be isolated with a minimum of interruption to service on the remainder of the distribution system. This paper reviews the method of achieving this end as employed on naval vessels and the tests conducted to demonstrate that selective operation of the protective devices function in accordance with the intended design on the completed installation. In order to discuss clearly the protective system on shipboard, the particular problems of shipboard installations are examined. It is considered that the new and novel feature brought out in this paper is the method of testing the system in order to demonstrate selective operation in accordance with the intended design.

Objective

Paragraph 53.09 of reference 1 states the following relative to the general design requirement for the protection of an a-c distribution system:

"*System Protection.* This should include providing suitable protective devices for each electric circuit and each unit of electric generating and power consuming equipment. The selection, arrangement, and performance of the various protective devices should be as recommended herein, and such as to provide complete and co-ordinated automatic protective arrangement having the following characteristics:

"(a) Maximum continuity of service under fault conditions through the selective operation of the various protective devices; that is, the isolation of a fault with the least interruption of service on the remainder of power distribution system, particularly those circuits affecting propulsion auxiliaries.

"(b) High-speed clearance of low impedance faults in order that fault currents of large magnitude will cause minimum damage to the system and equipment and minimize the hazard of fire.

"(c) Maximum protection of electric apparatus and circuits from damage under fault conditions, through the co-ordination of the electrical characteristics of the circuit or apparatus and the tripping characteristics of the protective devices."

The Bureau of Ships Specifications[2] state the following relative to the protection of power distribution systems:

"*General Design Requirements.* Each electric circuit and each unit of electric generating and power consuming equipment shall be provided with suitable protective devices as specified herein. The selection, arrangement, and performance of the various protective devices shall be such as to provide a complete and co-ordinated protective system having the following characteristics:

"High-speed clearing of all low impedance faults in order to minimize damage to the system and apparatus under fault currents of large magnitude.

"Maximum continuity of service under fault conditions through the selective operation of the various protective devices; that is, the isolation of any fault with the least interruption of service on the remainder of the power distribution system.

"Maximum protection of electric apparatus and circuits under fault conditions through the co-ordination of thermal characteristics of the circuit or apparatus and the tripping characteristics of the protective devices.

"Adequate interrupting capacity in all circuit interrupting devices or the provision of suitable back-up protection in such cases where the interrupting capacity of the device may be exceeded.

"Adequate thermal capacity in all the various circuit protective and switching devices for operation under normal loads, faults, and abnormal service conditions."

From a comparison of the two quoted general design requirements it may be seen that the ultimate end in view is essentially the same for both specifications.

Selective Tripping

Selective tripping is accomplished by the use of an inverse time delay on all circuit breakers that may be in a distribution system. This time delay is in the order of cycles and, as will be seen, is not always necessary for the protective devices that feed individual loads. To achieve selectivity, the time-current characteristics of each protective device must be such that for any possible fault current the time delay on a given circuit breaker exceeds the time delay and interrupting time of any circuit breaker that receives its power for distribution via the given circuit breaker (see Figure 2).

For an ideal selective tripping system each circuit breaker should be capable of interrupting the maximum available rms short-circuit current that may exist under any fault condition at the point in the distribution system where the protective device is located. If a protective device does not have sufficient interrupting capacity for the maximum available rms short-circuit current, it is necessary to provide back-up protection in the form of an instantaneous trip on the protective device that feeds the protective device that has insufficient interrupting capacity. This instantaneous trip is set to trip the so-called back-up circuit breaker instantaneously on all fault currents of magnitude greater than the interrupting capacity of the circuit breaker being backed up. Referring to Figure 2, if the circuit breaker represented by curve D has an interrupting capacity of only 15,000 amperes and the maximum available rms short-circuit current at the point in the distribution system where circuit breaker D is located is 40,000 amperes, it is necessary to set circuit breaker C to operate instantaneously on all fault currents above 15,000 amperes. Actually, because of manufacturing tolerances, the circuit

Paper 48-225, recommended by the AIEE marine transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted July 14, 1948; made available for printing September 3, 1948.

J. R. Cole is a marine electrical engineer with the Bureau of Ships, Navy Department, Washington, D. C.

breaker is set to operate instantaneously at 13,500 amperes. The time current characteristic for circuit breaker *C* is represented by curve *CFI*. It may be seen readily from Figure 2 that this arrangement does not provide for selectivity between circuit breaker *C* and *D* under fault conditions where the magnitude of the fault is above 13,500 amperes.

Shipboard Problems in Obtaining Objective

The problems involved in shipboard distribution are considerably different from those involved for shore installations. Shore electric-power systems consist of a network of power stations linked together so that in case of temporary loss of a local power plant the local power demands will be supplied by other plants connected to the system. Further, the capacity of each plant is only a small percentage of the total generator capacity interconnected by the network. A ship is entirely dependent upon its own plant and in case of operating difficulties cannot look to outside activities to supply power or to assist in returning the plant to operation.

A typical 440-volt a-c shipboard power distribution system is shown in Figure 1. It is essentially a radial distribution system with bus tie circuits for connecting the different switchboards. There may be one or two generators feeding each switchboard and as many as eight switchboards. The sizes of these generators range from 60 to 2,000 kw. Therefore, in view of the relatively close coupling between the generators and the loads and the high decrements in the short-circuit currents, it may be seen that short-circuit currents of considerable magnitude have to be successfully interrupted. However, where distribution panels are located at considerable distance from the switchboard, or where a transformer is in the circuit or in some cases on ships with generators of low capacity, it is necessary to make sure that the minimum short-circuit current will be of sufficient magnitude to operate the instantaneous trip device on the type *AQB* circuit breakers.

The exigencies of shipboard service with the possibility of damage to relay circuits makes it undesirable to depend upon remote relaying circuits for selective operation. Therefore, the protective functions should be an integral part of the circuit breaker or by an overcurrent relay located adjacent to the circuit breaker.

The space and weight requirements for the electrical distribution system must be kept as small as possible on a naval vessel. As will be seen later on, this makes it necessary to feed individual loads from the type *AQB* circuit breakers with some sacrifice in selective operation where the available short-circuit current is above the interrupting capacity of the type *AQB* circuit breakers. This makes it necessary also to feed a power panel containing a number of type *AQB* circuit breakers, via a type *AQB* circuit breaker. Since the type *AQB* circuit breaker depends upon instantaneous trip for all low impedance faults, both the circuit breaker in, and the circuit breaker feeding, the power panel may be interrupted by a fault on a circuit emanating from the power panel.

On shipboard power systems, the locked rotor current of large induction motors may be as much as 60 to 100 per cent of the full load current of one generator. As a consequence, it is necessary that the time-current characteristics of the protection devices have a definite relationship to the time-current characteristics of the motor starting currents. The induction motors also have a transient under starting which is as much as 1.8 times the locked rotor current. In the application of type *AQB* circuit breakers for the protection of individual motor loads, it is necessary that the instantaneous overcurrent trip of the type *AQB* circuit breaker be set high enough to prevent the circuit breaker from being tripped on the motor starting transient.

In a manner similar to an induction motor, a transformer has an exciting current transient. It has been found that an instantaneous trip setting of 12 times the full load rating of a delta transformer bank is sufficient to prevent tripping of a circuit breaker feeding a transformer due to the exciting current transient.

Protective Devices Employed on Naval Vessels

The following types of protective devices are employed on naval vessels: type ACB circuit breakers; type AQB circuit breakers; fuses; and overload relays in motor controllers.

Type ACB Circuit Breakers

This is an air-quench type circuit breaker having an open metallic frame and one or more of the following protective functions and attachments integral with the circuit breaker generally employed for protection of the distribution system:

1. Long-time delay overcurrent protection.
2. Short-time delay overcurrent protection.
3. Instantaneous overcurrent protection.
4. Shunt trip.

Figure 1. Schematic diagram of a typical ship's a-c power distribution system

The shunt trip on these circuit breakers may be operated by one or more relays with the following protective functions:

1. Reverse power protection.
2. Short-time delay overcurrent protection.
3. Long-time delay overcurrent protection.
4. Overpower protection.

It is desirable that the short-time delay overcurrent protection, the long-time delay overcurrent protection, and instantaneous overcurrent protection be integral with the circuit breaker for the reasons discussed previously and because of the problem of securing a suitable reliable source of tripping energy and the saving of space and weight due to the elimination of relays and associated equipment. The use of separate relays has been limited to short-time delay and long-time delay overcurrent protection on circuit breakers of 3,000-amperes, frame size or over when employed for generator or bus tie protection. In these cases, the exciter d-c voltage has been employed for the tripping energy.

The short-time delay overcurrent device provides inverse time delay at three different time settings, number 1, for minimum operating time (for use as feeder type *ACB* circuit breaker), number 2, for intermediate time (for bus tie protection), and number 3, for maximum operating time (for generator protection). The number-1 time-current trip band has a minimum time delay of three cycles (0.05 second) for any current up to 20 times the trip coil rating, but not exceeding 13,500 amperes. The number-3 time-current trip band has a maximum time delay of not greater than 24 cycles (0.40 second) for any current setting above 250 per cent of the pick-up current setting of the short time delay trip device. The number-2 trip band has time-current characteristics such that it will fit in between the number-1 and number-3 band in such a manner that there is a minimum

separation of one cycle (0.0167 second) between adjacent time-current trip bands. The pick-up current setting is capable of being adjusted from 200 per cent to 1,000 per cent of the trip coil rating.

The long-time delay overcurrent trip device provides an inverse time delay extending up to at least 800 per cent of the trip coil rating with a time delay of not less than 30 seconds at 125 per cent of the pick-up current value at the minimum pick-up settings. The pick-up current setting for this device is readily adjustable for any current from 150 to 300 per cent of the trip coil rating.

Curves *A*, *B*, and *C* on Figure 2 are typical type *ACB* circuit breaker time-current characteristic curves. Actually, the time-current tripping characteristics are bands instead of lines as indicated in Figure 2. This is a current band of approximately ± ten per cent of the mean. The type *ACB* circuit breakers are available in frame sizes with characteristics shown in Table I.

Type AQB Circuit Breakers

This is an air-quench type circuit breaker in a supporting and enclosing housing of insulating material having the following protective functions and attachments integral with circuit breaker; long time delay overcurrent protection; and instantaneous overcurrent protection.

Curve *D* in Figure 2 is a typical time-current characteristic curve for a type *AQB* circuit breaker. The long time delay is set to trip in 25 seconds ± 25 per cent at a current of 600 per cent of circuit breaker element rating, to trip in less than one hour at a current of 225 per cent of element rating and to trip in more than one hour at a current of 150 per cent of element rating. In standardizing the time-current characteristics of this long-time delay overcurrent protection, an effort has been made to provide a maximum protection for cable based on limiting the copper temperature rise to a value just below the temperature at which the insulation would be damaged. These circuit breakers are standardized in frame sizes based on maximum continuous current-carrying capacity. Table II shows the interrupting rating and approximate dimensions of the different frame sizes. Standardized element ratings are provided for these circuit breakers. The standard elements are manufactured with two different instantaneous trip ratings, one set to trip at 600–700 per cent of the element rating and the other, in most cases, set to trip at 1,200–1,400 per cent of the element rating.

Figure 2. Time-current characteristics of circuit breakers in Figure 1

Fuses

When employed for protection, fuses are generally used in conjunction with a switch. However, because of their limited interrupting capacity and other considerations discussed previously,[3] their use is generally limited to lighting circuits and nonvital power circuits.

Overload Relays in Motor Controllers

The function of this relay is to furnish overload protection for a given motor and therefore does not enter into the problems of system protection as discussed herein

Arrangement of Devices to Obtain Selectivity

As stated previously selective operation is achieved by the provision of protective devices that have time-current characteristics arranged so that the time delay of any given circuit breaker exceeds the time delay and interrupting time of any circuit breaker that receives its power for distribution via the given circuit breaker. The protection afforded by circuit breakers is essentially intended as fault protection and is not designed to give overload protection. The overload relays in the controllers are depended upon for overload protection of motors, and the operator is depended upon to take care of any overload on the generators.

Table I. Minimum Interrupting Rating, Short Time Thermal Capacity, and Dimensions of Type ACB Circuit Breakers

Frame Size, Amperes	Maximum Interrupting Rating, Amperes	Short Time Thermal Capacity, Amperes	Approximate Size of Circuit Breakers in Inches			Weight Each, Pounds
			Height	Width	Depth	
225	20,000	3,500	17	12	8¼	61
600	40,000	18,000	24	13	13	95
1,600	60,000	24,000	27	22	16	260
3,000	75,000	36,000	35	34	22	600
4,000	100,000	50,000	39	35	22	635

Table II. Maximum Interrupting Rating and Dimensions of Type AQB Circuit Breakers

Frame Size, Amperes	Maximum Interrupting Rating, Amperes	Approximate Size in Inches			Weight Each, Pounds
		Height	Width	Depth	
100	15,000	10	5	4 1/16	9 1/4
225	20,000	15 1/4	9	4 15/16	26
600	30,000	22	9	5 1/4	60

Some degree of overload protection is afforded by the long time delay overcurrent protection of the circuit breakers; however, the primary function of the long time delay overcurrent protection is to provide high impedance fault protection.

Until the magnitude of the short-circuit current is known, it is not possible to apply protective devices in a manner to assure adequate protection. The methods of calculating the magnitude of short-circuit currents in low-voltage distribution systems are established and will not be discussed here; however, the following is a list of short-circuit calculations that are necessary for the correct application of protective devices:

1. *Maximum Available rms Short-Circuit Current (Average of Three Phases).*

This current which is the basis for interrupting rating of low voltage (600 volt or less) air circuit breakers, is the average value of the maximum available rms short-circuit currents which occur in the three phases during the first cycle after inception of the short circuit. This calculation is based upon the maximum expected parallel generator capacity plus the contribution of the maximum induction and synchronous motor load connected to the system under this condition. In making these calculations, all generators and significant circuit impedance up to the line terminals of the circuit breaker under study are considered.

2. *Maximum Available rms Asymmetrical Short-Circuit Current.*

This current which is the basis for the interrupting rating of fuses, and the short time current rating and mechanical strength of switches, cables, bus work and circuit breakers, is the total rms current at one-half cycle in the phase carrying the maximum asymmetrical current. This calculation is based upon the maximum expected parallel generator capacity plus the contribution of the maximum induction and synchronous motor load connected to the system under this condition. In making these calculations, all generator and significant circuit impedances up to the line terminals of the device under study are considered.

3. *Minimum Available rms Asymmetrical Short-Circuit Current at the Point of Application of Each Circuit Breaker.*

This quantity is required to determine that the trip settings of all the protective devices are within the available fault current under all conditions of operation. This current is determined on the basis of one generator of the lowest rating connected to the systems under consideration. It is assumed that the contribution of the induction and synchronous motorload is negligible. The fault is considered to be located on the line side of the next circuit breaker beyond the one in question and the total impedance to the point of fault includes the resistance and reactance of the circuit breaker in question.

4. *Maximum rms Asymmetrical Short-Circuit Current of Each Generator.*

This quantity is required with regard to the pickup current setting of the instantaneous over-current trip device on the generator circuit breaker. This current is determined on the basis of the generator being short circuited from rated load at rated power factor. This short circuit is assumed to be located on the line terminals of the generator circuit breaker.

5. *Maximum Sustained rms Short-Circuit Current of Each Generator.*

This quantity is required with regard to the pick-up current setting of the short time delay overcurrent device of the generator circuit breaker. It is determined on the basis of a short circuit at the line terminals of the generator circuit breaker and includes the effect of the generator voltage regulator with field hot.

For the purpose of this study the circuits that require protective devices may be divided into four categories as follows: single load circuits; feeder circuits; bus tie circuits; and individual generator circuits.

Protection of Single Load Circuits

The single load circuits are those circuits supplying power to a single unit of power consuming equipment (motor, transformer, heater, and so forth). The type *AQB* circuit breaker is employed for the protection of these circuits except that in certain cases fused switches are used for the protection of nonvital loads. These fused switches are limited to nonvital loads where the fuse size does not exceed 60 amperes and the maximum available rms asymmetrical short-circuit current does not exceed the interrupting capacity of the fuse. The interrupting capacity of fuses varies from 3,000 to 8,000 amperes depending upon the fuse size. When fuses are installed in large capacity systems, they are always fed via a type *AQB* circuit breaker to insure adequate isolation of heavy faults on circuits protected by fuses. For noninductive loads, fuse sizes are selected at approximately 125 per cent full load current of the circuit. For motor loads fuse sizes are 2/3 locked rotor current. Navy controllers as a rule do not employ fuses.

The type *AQB* circuit breaker which is employed in most cases for the protection of individual load circuits is provided with long-time delay overcurrent and instantaneous overcurrent protective features. The element rating and the instantaneous overcurrent trip setting must be taken into consideration when applying type *AQB* circuit breakers for the protection of individual load circuits. The element rating is equal to, or the next size above, the full load current of the circuit. As pointed out in the section, "Protective Devices employed on naval vessels," the type *AQB* circuit breakers are standardized with a selection of two instantaneous overcurrent trip settings for each element rating; that is, 600-700 per cent of element rating and 1,200-1,400 per cent of element rating. The instantaneous overcurrent trip is selected to meet the following requirements:

1. So it will exceed the maximum inrush current of the circuit; that is, the induction motor starting current transient or transformer exciting current transient. It has been found that an instantaneous overcurrent trip setting of 1,200 per cent of the circuit-breaker element rating when selected in accordance with the foregoing will provide an instantaneous trip above the transient current of an induction motor or a transformer. Where reduced voltage closed transition starting is used, the instantaneous overcurrent trip setting may be reduced in proportion to the reduction in the steady-state starting current taken from the line.

2. In order to assure that the circuit breaker will trip instantaneously under short-circuit conditions, the instantaneous overcurrent trip setting of the circuit breaker should not be greater than 60 per cent of the minimum available rms short-circuit current at the point of application of each circuit breaker.

3. The instantaneous overcurrent trip setting is selected as low as is compatible with the foregoing requirements using standard trip settings so as to have the greatest band between this circuit breaker and the time-current characteristics of the circuit breaker feeding this circuit breaker.

In some instances, the minimum and maximum requirements for the instantaneous overcurrent trip settings have been found to be somewhat incompatible. However, in general, a satisfactory arrangement can be realized by a suitable arrangement of the circuits involved.

Protection of Feeder Circuits

Feeder circuits are circuits supplying power to a group of loads (two or more). These circuits may emanate from a load-center power-distribution panel or from a generator and distribution switchboard and are supplied through either type *AQB* or type *ACB* circuit breakers.

Type AQB Circuit Breakers. All feeder circuits emanating from load-center power distribution panels are supplied through type *AQB* circuit breakers. Where the maximum available rms short-circuit current is within the interrupting rating of a type *AQB* circuit breaker or where adequate back-up protection is provided in the form of a type *ACB* circuit breaker, the type *AQB* circuit breaker may be used to supply feeder circuits emanating from the generator and distribution switchboard. In all of the preceding applications, the type *AQB* circuit breaker is provided with long-time delay and instantaneous overcurrent protective features. The element rating and the instantaneous overcurrent trip setting must be taken into consideration when applying type *AQB* circuit breakers in this manner. The element rating is equal to or next in size above the resultant load current of the circuit. The instantaneous overcurrent trip is selected to meet the following requirements:

1. It should exceed the arithmetical sum of 1.6 times the steady-state starting current of the largest motor plus the full load currents of the balance of the loads on the circuit so as to prevent the possibility of the circuit breaker being tripped falsely under normal operating conditions.

2. In order to assure that the circuit breaker will trip instantaneously under all short-circuit conditions, it must not be greater than 60 per cent of the minimum available rms short-circuit current at the point of application of each circuit breaker.

3. It should be such that it will co-ordinate with the time-current characteristics of the circuit breaker feeding this circuit breaker and with any circuit breaker being fed by this circuit breaker.

The employment of the type *AQB* circuit breakers for the protection of feeder circuits results in the installation of two type *AQB* circuit breakers in series, both of which depend upon instantaneous overcurrent trip for protection against short-circuit faults. In a great many cases the magnitude of the available short-circuit current on a fault in a circuit protected by two type *AQB* circuit breakers in series will be greater than the instantaneous overcurrent setting of both devices. Accordingly, there is little likelihood of selectivity between these devices. Because of space and weight considerations, it is necessary to use type *AQB* circuit breakers for the protection of group feeders. However, every effort is made to limit the type *AQB* circuit breakers in series to two, and to group the loads on feeders so as to limit the interrupting of like services that might result from a fault on a single load circuit interrupting the group feeder circuit breaker also.

Type ACB Circuit Breakers. All feeder circuits emanating from generator and distribution switchboards where the maximum available rms short-circuit current exceeds the interrupting rating of a type *AQB* circuit breaker are supplied through type *ACB* circuit breakers having the required interrupting rating. In some cases, where the space and weight limitations of the vessel will permit, type *ACB* feeder circuit breakers are employed because of the additional selective protection that they afford even though they are not required for back-up protection. In the application of type *ACB* circuit breakers for the protection of feeder circuits, the circuit breakers are provided with long-time delay, short-time delay and instantaneous overcurrent protection.

The long-time delay overcurrent protection is to provide a maximum degree of high impedance fault protection. To achieve this, the long-time delay device is set to pick-up at approximately 150 per cent of the resultant load current on the circuit, and the time-current characteristics of the long-time delay are selected such as to exceed the time-current characteristics of the maximum normal current inrush of the circuit.

The function of the short-time delay overcurrent protection is to provide for high clearing of all faults on the feeder circuits, and to provide selective operation between the type *ACB* feeder circuit breakers and the type *AQB* circuit breakers at the power-distribution panel supplied by the feeder circuit. This protective device is generally set to pick-up at not less than 120 per cent of the highest instantaneous overcurrent setting of any type *AQB* circuit breaker connected to the feeder circuit protected by the given type *ACB* circuit breaker in order to assure selectivity with the type *AQB* circuit breaker. However, it may be seen from a study of the curves on Figure 2 that a large degree of selectivity is realized if the instantaneous trip of the type *AQB* circuit breaker is above the pick-up of the short time delay on the type *ACB* breaker; that is, nonselectivity would result only for fault currents of the values of the band of overlap of the instantaneous trip of the type *AQB* circuit breaker and the pick-up of the short-time delay device on the type *ACB* circuit breaker. In order to eliminate the possibility of the feeder circuit breaker tripping under inrush current conditions, the short time delay is set to pick-up at not less than 125 per cent of the maximum normal inrush current of the feeder circuit. In order to provide selectivity with the bus tie circuit, the short-time delay device should be set to pick-up at not more than 80 per cent of the pick-up of the short-time delay device on the bus-tie circuit breaker. As discussed in the section on protective devices, the time-current characteristics of the short-time delay overcurrent device is such as to give a minimum time delay of 0.05 second on all current values up to the interrupting rating of the type *AQB* circuit breaker, in order to assure that this device will not trip the type *ACB* circuit breaker before a fault is cleared by the type *AQB* circuit breaker.

Instantaneous overcurrent protection is provided in the feeder type *ACB* circuit breaker where the interrupting rating of any of the type *AQB* circuit breakers is less than the maximum available rms short-circuit current and/or where the maximum available rms asymmetrical short-circuit current may exceed the short time rating of the type *ACB* feeder circuit breaker. When required as back-up protection for type *AQB* circuit breakers, the instantaneous overcurrent device is set to trip at 90 per cent of the interrupting rating of the smallest type *AQB* circuit breaker connected to the feeder. Where required, because the maximum available rms asymmetrical short-circuit current exceeds the short time rating of the circuit breaker, the instantaneous overcurrent trip is set to trip at the short time rating of the circuit breaker. If required for both of the foregoing reasons, the instantaneous trip is set to trip at the lower of the above two values.

Protection of Bus Tie Circuits

Type *ACB* circuit breakers provided with long-time delay overcurrent, short-time delay overcurrent, and sometimes instantaneous overcurrent protection are provided for the protection of bus tie circuits.

The function of the long-time delay overcurrent protection is to provide a maximum degree of high impedance fault protection on the bus tie circuit. The pick-up setting of the device is set at approximately 150 per cent of the resultant load current of the circuit; however, it must be not less than 123 per cent of the

Figure 3. Selective tripping demonstration procedure

highest pick-up current setting of the long-time delay overcurrent trip device on the feeder circuit breaker and not more than 80 per cent of the pick-up current setting of the long-time delay overcurrent device on the generator circuit breaker, in order to assure selectivity with the feeder circuit breaker and the generator circuit breaker.

The function of the short-time delay overcurrent protection is to provide for the high-speed clearing of all faults on the bus tie circuit and the switchboard busses connected thereto and selective operation between the bus tie circuit breaker and the feeder circuit breakers for all faults on feeder circuits. This protective device is set to pick-up at a current of not more than 80 per cent of the pick-up current setting of the generator circuit breaker. As discussed in the section on protective devices, the time-current characteristics of this protective device are such that for any value of current in excess of the pick-up current setting the time delay of the bus tie circuit breaker exceeds the sum of the time delay and interrupting time of any feeder circuit breaker.

Instantaneous overcurrent protection is provided on bus tie circuit breakers only when the maximum available rms asymmetrical short-circuit current exceeds the short time rating of the bus tie circuit breaker, in which case, it is set at the latter current value.

Protection of Generators

Ship's service generators are connected to the ship's service distribution system through type *ACB* circuit breakers provided with long time delay overcurrent, short time delay overcurrent, and, in most cases, instantaneous overcurrent protection and reverse power protection.

Long time delay overcurrent protection is provided to prevent excessive temperature rise of the generator on extreme conditions of overload only. Since most ship's service generators have a load capacity of 150 per cent of full load for five minutes, this device is set to pick-up on a current approximately equal to but not less than 150 per cent of the generator full load current. The time-current characteristics of this device are such as not to exceed the normal inrush current to be supplied by the generator.

The function of the short time delay overcurrent protection is to provide for the high-speed clearing of all faults in the generator switchboard and for selective operation between the generator circuit breaker and the bus tie and feeder circuit breakers for all faults. This protective device is set to pick-up at a current value of not more than 80 per cent of the maximum sustained rms short-circuit current of the generator. As stated previously, the time delay of this device for any value of current above 250 per cent of the pick-up current is not greater than 24 cycles (0.40 second). Further, in the application of this device on a generator circuit breaker, the time delay is set such that, for any value of current in excess of the pick-up current setting, the time delay of the generator circuit breaker is greater than the sum of the time delay and interrupting time of the bus tie circuit breaker at the corresponding value of current.

Instantaneous overcurrent protection is provided whenever the short time rating of the generator circuit breaker may be exceeded in the particular application and/or when more than two generators may be operated in parallel. When provided, this device is set to trip at a current approximately equal to but not less than 120 per cent of the maximum rms asymmetrical short-circuit current of the generator. The short time ratings of the standard type *ACB* circuit breaker are such that 120 per cent of the maximum rms asymmetrical short-circuit current of a generator will not exceed the short time rating of a generator circuit breaker. This instantaneous overcurrent protection is provided to isolate the generator and generator cable in case the generator cable is short circuited. Under these circumstances, the fault current for tripping the protective device is supplied by the motor contribution and the other generators in the circuit.

Reverse power protection is provided on all generators that are required to operate in parallel with other power sources. The purpose of the reverse power protection is to prevent damage to the prime mover in case of loss of prime mover power and, in addition, to clear faults in the generator and generator cables. This protection is provided by means of a relay that operates the generator circuit-breaker a-c shunt trip. In order to prevent the synchronizing power transients from causing false operation, the reverse power relay is provided with inverse-time-power characteristics such that when energized at rated voltage the relay will trip in approximately ten seconds with reverse power equal to five per cent of the generator rating.

Shipboard Tests

After the distribution system is installed aboard the vessel, tests are conducted to demonstrate selective operation in accordance with the intended system design. These tests are conducted with a ship's generator furnishing the fault current. A bolted fault is simulated by a quick-acting switch. Figure 3 shows the connections for a complete set of tests on one switchboard, and Table III is a tabulation of a complete set of tests for one switchboard. The minimum number of tests conducted are as follows:

1. Test for selectivity between each generator circuit breaker on each switchboard and each bus tie circuit breaker connected to that switchboard (demonstrations 5 and 6 in Table III).

2. Test for selectivity between the circuit breakers in each bus tie feeding each switchboard and a feeder type *ACB* circuit breaker on that switchboard (demonstration 4 in Table III). The feeder circuit breaker with the highest short time delay overcurrent pick-up setting is selected for this test on each switchboard.

3. Test for selectivity between each generator circuit breaker on each switchboard and a feeder type *ACB* circuit breaker connected

Table III. Selective Tripping Demonstration Procedure

Demonstration Number	Fault Location	Circuit Breakers Closed Before Demonstration	Operate Generator Number	Demonstrates Selectivity Between
1	1	F, G, H	4	H and G
2	2	F, G	4	G and F
3	2	E, G	3	G and E
4	2	B, C, D, G	2	G and D or C
5	3	F, D	4	D and F
6	3	E, D	3	D and E

to the switchboard being tested (demonstrations 2 and 3 in Table III). It is obvious that this test may be omitted in all cases where demonstrations 4, 5 and 6 adequately prove selectivity between generator and bus tie and between bus tie and feeder type *ACB* circuit breakers.

4. Test to demonstrate selectivity between a feeder type *ACB* circuit breaker and a feeder type *AQB* circuit breaker on each switchboard (demonstration 1 in Table III). The combination of feeder type *ACB* and type *AQB* circuit breaker selected for this test on each switchboard is the one that comes closest to having overlapping time-current characteristics.

It is evident that on vessels which have the type *AQB* feeder circuit breakers connected directly to the switchboard bus the test is modified accordingly to suit the actual designed distribution arrangement.

These tests are conducted with only one generator supplying the fault current and the fault is applied when the generator is operating at no load. It is recognized that there is a wide range of possible fault currents that the circuit breakers may be called upon under actual operating conditions to interrupt selectively depending upon the number of generators in operation and the motor load being fed by the generators. Accordingly, the best that the shipboard test can do is to demonstrate selectivity at one magnitude of fault current. In most cases this fault current is of the magnitude required to cause the type *ACB* circuit breakers to operate in the short time delay overcurrent band. Since it can be assumed that each circuit breaker will have essentially the same slope of its time-current curve, this test can be considered an adequate demonstration of selectivity.

Discussion

J. W. Simpson (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The author's paper is an excellent review of the subject. The fact that the Navy has several vessels in operation with systems embodying essentially the same protection system described, lends considerable weight to the statements made in this paper as operating experience is the acid test for any protective system.

I would like to take this opportunity to make several comments which occur to me. It is important to remember that the current time characteristics of circuit breakers are bands rather than lines. The band furthermore is not the difference between the maximum and minimum operating times. The upper limit of the band is the maximum operating time of the circuit breaker and the lower limit is the reset time, that is the maximum time the circuit breaker will carry the given current and still reset when the current is suddenly reduced to the continuous current rating of the circuit breaker.

It should also be kept in mind that when circuit breakers can only open after a time delay both thermal and mechanical stresses become much more important. In some applications, the short time rating should be equal to the interrupting rating of the circuit breaker. In general for shipboard application the 1,600-ampere frame circuit breaker should have a short time rating of 60,000 amperes, whereas the 600-ampere frame need only have a short time rating of 18,000 amperes or 30 times coil rating. This is due to the fact that the interrupting rating of the 600 ampere is proportionately higher and to the fact that no more than two generators ever feed through a 600 ampere bus tie breaker. Generator circuit breakers need never have instantaneous trips set higher than 120 per cent of maximum assymetrical rms short circuit current of one generator. Feeder breakers need never have their instantaneous trips set higher than 1,200 to 1,400 per cent of coil rating or 13,500 amperes. In the overload range circuit breakers definitely are not selfprotecting. For example if the long-time delay pickup is 300 per cent, the circuit breaker can be damaged by a current of 250 per cent of its rating flowing continuously.

Cole states that the instantaneous trip setting of *AQB* circuit breakers should not be greater than 60 per cent of the minimum available rms short-circuit current at the point of application. This seems to be a good compromise, however, if there is any appreciable fault impedance the circuit breakers still may not trip instantaneously.

Cole states that if a protective device does not have sufficient interrupting capacity for the maximum available rms short-circuit current, back-up circuit breakers should be provided. I believe that there should be a limit to the disparity in interrupting rating between the back-up and feeder circuit breakers. For example a circuit breaker having an interrupting capacity of 100,000 amperes probably would not provide much back-up protection for a 15,000 ampere interrupting rating circuit breaker. The exigencies of shipboard installation might make it desirable, however, to permit a somewhat greater ratio than the two-to-one required by present National Electrical Manufacturers Association rules.

In the design of protective systems as well as in the judging of their performance, it must be remembered that circuit breakers with no overlapping in their tripping bands may still not be selective if the circuit breaker with the longer desired tripping time should be carrying additional parallel load. This is particularly true where the tripping curves are very inverse.

In connection with the shipboard tests described by Cole, it might be well to raise the question as to what is the real objective of such tests. True, they give an indication of adequate selectivity, but they are far from comprehensive enough to be conclusive and therefore may be misleading, in that they give false assurance of a satisfactory protective system.

J. R. Cole: The first four paragraphs of Simpson's comments deal with the limitations of circuit breakers. The selective tripping as discussed in my paper is based on the application of these devices with their inherent limitations. As pointed out in my paper, these limitations in the protective devices, such as the short-time thermal capacity of type *ACB* circuit breakers mean some compromise in the actual resultant selective operation. As stated under "Arrangement of Device to Obtain Selectivity," the primary function of the long-time delay over-current protection is to provide high-impedance fault protection, not overload protection as implied in paragraph 4 of Simpson's remarks. It is realized that one of the limitations of the type *ACB* circuit breaker is its short-time thermal capacity. Steps are presently being taken to increase this thermal capacity without increasing the inherent operating time of the circuit breaker.

If the fault impedance on a circuit protected by a type *AQB* circuit breaker is of such magnitude, that the fault current will not trip the circuit breaker instantaneous trip when the circuit breaker is applied in accordance with the rules set forth in my paper, the circuit breaker thermal trip must be depended upon for circuit protection. Experience shows that this will seldom happen in shipboard installations when the circuit breaker instantaneous trip is not greater than 60 per cent of the minimum available rms short-circuit current at the point of application of each circuit breaker.

Simpson states that "it must be remembered that circuit breakers with no overlapping in their tripping bands may still not be selective if the circuit breaker with the longer desired tripping time should be carrying additional parallel load." This might be true if there were no motors in this parallel load. In shipboard applications, this parallel load will consist at least partially of motors. These motors will contribute partially to the fault current, thus lessening the current on the parallel circuit and increasing the fault current through the circuit breaker protecting the circuit which has the fault.

As stated, the shipboard selective tripping demonstrations do not attempt to duplicate all possible fault conditions or possible magnitudes of fault current or to check the calibration of the protective devices. These tests do demonstrate selectivity under certain possible operating conditions, they do indicate certain limitations, and they serve to provide information for future designs.

Ventilation of Rotating Electrical Equipment on Shipboard

A. M. HARRISON
MEMBER AIEE

ONE of the most important limitations to the capacity of electric machinery is the temperature of the windings. The temperature limit for electric machines depends on the class of insulation employed. The maximum hot-spot temperature limits of 105 degrees centigrade and 130 degrees centigrade for class *A* and *B* insulation respectively are well established. The limit for silicone insulation is not so definitely fixed, but 180 degrees to 200 degrees centigrade is being considered for hot-spot temperature.

There are many limitations other than temperature to be considered in the design of electric machinery. Some of these are power factor, efficiency, pull-out torque, overload capacity, commutation, and regulation. However, with class *A* and *B* insulation, temperature rise is one of the first limitations to be reached, so the problem of ventilation is of extreme importance. The use of silicone insulation has raised the temperature limits to the point where other limitations may occur first but good ventilation is still essential to obtain the best balanced design.

The importance of properly ventilating machines cannot be overemphasized. The more efficient the ventilation system can be made, the greater will be the output which can be obtained from a given amount of material, while still maintaining the temperature within proper limits. This, of course, is the ultimate aim of the designer and is extremely important on shipboard where space is usually at a premium.

It is the purpose of this paper to describe some of the methods used in ventilating various types of electric machinery.

When the temperature rise of a machine becomes constant, it means the heat is being absorbed by the cooling medium at the same rate at which it is generated. The rate at which heat is absorbed by the cooling medium is a function of the watts per square inch of exposed surface, the average temperature difference between the cooling medium and the surface temperature, and the velocity at which the cooling medium passes over the exposed surfaces. All of these factors are quite variable throughout the machine and it would be extremely difficult to determine the temperature rise for each individual design from these considerations alone.

The best possible means of determining the proper amount of air required for a given temperature rise is from tests of previously designed similar machines. It has been found as the result of many tests that on the average for 40 degrees centigrade rise machines, approximately 135 cubic feet per minute per kilowatt loss is required. This gives about 13 degrees rise of cooling air, using the relation that

$B = 1.765W/\theta_a$ where

V = volume of air in cubic feet per minute
W = watts loss to be absorbed by air
θ_a = temperature rise of air in degrees centigrade

Similarly, it has been found that for 70 degrees rise machines approximately 70 cubic feet per minute per kilowatt loss is required and for 85 degrees rise about 55 cubic feet per minute per kilowatt loss. These values correspond to rises of 25 degrees centigrade and 32 degrees centigrade in the cooling air respectively. It should be noted that these are approximate values only and may vary ±10 per cent depending on the efficiency of the ventilating system. The volume of air required is not inversely proportional to the temperature rise due to the fact that the surface heat transfer varies about as the 8/10 power of the air velocity.[1]

The foregoing values of air volume per kilowatt loss are used when machines are force ventilated. When machines are self-ventilated, the air volume circulated through the machine is fixed by the speed. Obviously self-ventilated machines must be designed so the losses can be dissipated with the natural air volume and still not exceed the temperature limits.

To circulate the cooling medium in the most efficient manner, rotating electric machines are designed to take advantage of the natural fan action of the rotating element. Electric machines are constructed usually of laminations to reduce core losses and this type of construction lends itself very well to radial ventilation. By building the iron in packages with vent spacers at regular intervals, radial ducts are formed. This increases very materially the area of the core in contact with the cooling medium and the area available for dissipating heat.

It is a well known fact that the heat conductivity along the laminations is about 50 times as great as the conductivity across the laminations. This would seem to indicate that axial ventilation, where air is blown across the ends of the laminations, would be better than radial ventilation. However, this is not true because the radial vents make better use of the fan action of the rotor. Also, with proper sized packages of laminations, the area of the ducts is so much greater than the circumferential area and the length of the path for the heat to travel is so much smaller, that a very large portion of the heat is conducted across the laminations. The heat is dissipated in the ducts in spite of the poorer heat conductivity across the laminations. The greater the radial depth of punchings, the more nearly this is the case because the circumferential

Paper 48-226, recommended by the AIEE marine transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 27, 1948; made available for printing August 20, 1948.

A. M. HARRISON is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1 (left). Natural air paths of an open type d-c machine

Figure 2. Natural air paths of an open type d-c machine with antirecirculation end bell

area remains almost constant, regardless of the punching depth; whereas, the duct area increases with increase in the depth of laminations.

Improved ventilation of machines can be obtained by directing the air so it is most effective. This can be done by designing baffles and end bells. Blowers are frequently used either as an integral part of the rotor or, as in the case of slow speed machines, the blower may be separately driven and external to the machine with suitable ducts for directing the air into and out of the machine.

The natural paths of the air flow for a simple open type d-c machine are shown in Figure 1. The end windings at the rear act as a radial blower, as do the ducts in the armature. If nothing is done to prevent it, some of the air recirculates and is again drawn into the rear-end winding. This makes the end windings hotter than necessary. By adding a single rear-end bell as shown in Figure 2, this recirculation can be prevented with a resultant decrease in temperature rise. The commutator necks act as a very effective blower and tend to pull air through the machine under the core from rear to front. The commutator necks also pull air across the commutator surface and so help to cool the commutator. This is shown in Figure 1.

Additional fan action can be obtained by installing blowers under the armature coils at the front and rear. Additional cooling can be obtained for the field windings by installing blowers at the extreme end of the armature windings and extending the rear-end bell slightly. Additional cooling of the commutator is accomplished by adding short vanes on the extreme front end of the commutator. The big advantage of the commutator vanes is not so much the increased blower effect, but the greatly increased radiating surface available for dissipating the commutator losses. With vanes about $1^1/_2$ inches wide and 2 inches in radial depth, the radiating surface per bar is more than doubled. Blowers can be brazed also to the necks to increase the radiating surface and thus lower the temperature rise. See Figure 3.

Shaft-mounted fans are sometimes used to obtain increased output when the natural ventilation is restricted by such things as drip-proof covers, semienclosing covers, splashproof machines, and so forth. Attached fans are used also when machines are totally enclosed using recirculated air and a heat exchanger. In such cases it is necessary for the attached fan to develop only the additional pressure required to take care of the pressure drop in the duct work and in the cooler since, on high-speed machines, the armature develops enough pressure to cool itself if the machine did not have any external restrictions. Obviously, attached fans are used only on machines where the speed is high enough to make a blower of this type effective. Where the rotation speed of the armature is not high enough to give a good blower design, the benefits of additional ventilation can be secured by using a separate motor driven blower. This type blower can be used either with a recirculated system, or in a system where the air is taken from the outside of the machine and discharged into the open after being forced through the machine by the blower. Figure 4 shows a slow-speed d-c dredge pump motor with a separate motor driven blower. The air is forced into the rear and discharged at the front. The front end is equipped with a drip-proof cover.

When attached fans are used, the fan may be mounted at the front or the rear of the machine. By mounting the fan at the front on d-c machines, the air paths are exactly the same as in the self-ventilated machine or in the natural direction of the air flow. In addition, the carbon dust from the commutator and brushes is drawn into the fan and not into the commutator risers and windings as is the case when the fan is at the rear of the machine. The length of the machine is about the same whether the fan is at the front or rear. With the fan at the front end, the commutator is cooled by air which is heated by the losses in the armature. Due to the fact that practically all the ventilating air is made to pass over the commutator, the temperature rise is about the same as the reverse air flow where the air temperature is lower but the volume of air is less. These two schemes of ventilation are shown in Figures 5 and 6. Locating the fan at the rear end of the armature has the advantage of giving a little better brush accessibility on small machines. On larger machines very good brush accessibility can be obtained even with the fan on the front end, as openings in the fan spokes can be used for getting at the brushes from the front, as well as the circumferential openings on the sides.

With a nonrecirculated system, the air

Figure 3. Cross section of d-c machine with internal blowers on armature and cooling fins added to back of commutator necks and front of commutator bars for additional cooling

Figure 5. Cross section of a d-c machine with fan at front, giving forward direction of air flow

is discharged radially all around the machine as shown in Figure 5. In the case of a recirculated system with a cooler, it is necessary to use a housing, preferably of the volute type, so all the air discharged from the blower can be collected efficiently and directed through the cooler. Such a ventilation scheme is shown in Figure 7. The cooler shown is of the double-tube type so a leaking tube will not allow water to get into the ventilating system. If the cooler is mounted away from the machine, coolers of the single-tube type of construction may be used.

If machines with a recirculatory system of ventilation have no filter, the carbon dust worn from the brushes will deposit on the windings, internal creepage surfaces of the machine, air ducts, and coolers. The advantage of the forward direction of air flow through the machine from rear to front is apparent in this case as a large portion of the dust will be deposited on the cooler and duct work before reaching the vulnerable front end of the machine. Back of the commutator necks is a very bad spot because it is a very difficult location to clean. Mechanical filters of the filter paper, glass wool or impingement type, while not completely effective, are very helpful in preventing the recirculation of brush dust. Electrostatic-type filters, such as the Precipitron, are very efficient in this respect but,

Figure 4 (left). D-c dredge pump motor with separate motor driven blower

Figure 6. Cross section of a d-c machine with fan at rear, giving reverse direction of air flow

Figure 7. D-c generator with recirculated air cooling system, consisting of attached fan, volute housing, precipitron, and cooler

Figure 9. Shipboard installation showing suction-type ventilation

due to the low frontal velocity required, are not very practical as a built-in part of the ventilating system for large machines, unless the space requirements are not limited. Figure 7 shows a practical installation of an electrostatic-type filter where the frontal area required is no larger than that required for the cooler. This machine is approximately 400 kw at 1,200 rpm.

If a machine is installed in a very oily atmosphere it may be necessary to take special precautions even when the machine is totally enclosed with a recirculating air system. There is always a certain amount of leakage in such a system and if nothing is done to prevent it, the atmosphere inside the machine will eventually have the same concentration of oil vapor as exists outside. A scheme which has been used successfully, is to open the machine to the outside through a Precipitron at lowest point of pressure in the enclosed system. This means that all other points in the system are above atmospheric pressure and the leakage therefore is outward at all points except the point where the air can enter through the Precipitron.

The filter will remove any oil vapor

Figure 8. Suction ventilation from front anti-recirculation rear end bell

Figure 10. Cross section of a salient pole a-c generator with recirculating air cooling system and built-in cooler

Figure 11 (left). Salient pole a-c generator with recirculating air cooling system and built-in cooler

Figure 13. Air paths through rotor of a typical a-c turbine driven generator

and the air in the enclosed systems will remain free of oil vapor. The amount of air entering through the filter is only the leakage and so the electrostatic filter can be very small. The pressure drop through this point in the system is essentially atmospheric. If it is necessary to have a duct of any length so some pressure drop is introduced at the air entrance, a small blower may be used to overcome this drop and "pump up" the system slightly so all air leakage is outward.

Electric machinery on shipboard is practically always installed in a more or less confined space. This means that forced ventilation is necessary in order to remove the losses from the machinery space even when it might not be necessary to force ventilate the machine for any other reason. If the hot air were not removed, the ambient temperature would rise to prohibitive values and even if insulation were used which could stand abnormal temperatures, it would be unsatisfactory from the standpoint of operating personnel. In such cases the so-called induced draft system of ventilation may be used. Figure 8 illustrates this type of ventilation schematically. The air enters at the rear through an ordinary antirecirculation type of end bell and a connection to an exhaust fan is made by means of a chimney at the top of a totally enclosing front end bell. An actual shipboard installation of this type is shown in Figure 9. Two machines have a common exhaust duct which draws the hot air out of the front end of the machines and discharges it above deck.

The illustrations used so far have all referred to d-c machines. The same fundamental principles apply, of course, to a-c machines. There are two main differences, and these differences modify the flow of the ventilating air. First, the stator of the a-c machines is laminated and this allows the air from the ventilating ducts to be discharged radially. This, of course, is not possible with the solid yoke of the d-c machine so that air must flow axially from rear to front. Second, the

Figure 12. Self cooled recirculating air system of a nonsalient pole a-c generator

Figure 14. Ventilation system for a large a-c propulsion motor with propeller type fan

Figure 15. Ventilation system for a large a-c propulsion motor with centrifugal-type blowers

Figure 17. D-c drip-proof, semienclosed pump motor

a-c machine, having no commutator, is symmetrical so air can flow from both ends and be discharged radially.

Figure 10 is a cross section of a salient pole a-c generator self-cooled with a recirculating air system and built-in cooler. The paths of the ventilating air are indicated by the arrows. The blower blades at each end of the rotor, as well as the rotor itself, force air into the air gap. It is then discharged radially through the stator vent ducts. Solid frame covers collect the air and direct it into the bottom of the cooler. The cool air is discharged from the top of the cooler, where half of it flows to the front and half to the rear, through suitable ducts directing the air back into the end bell and blower entrances. An illustration of such a machine, with all enclosures in place, is shown in Figure 11. A very similar type of ventilating scheme, except for a nonsalient pole a-c generator is indicated by Figure 12. The rotor of a machine of this type is rotating so fast that it is extremely effective in cooling itself providing suitable paths for air flow are arranged. Figure 13 shows the paths of air through the rotor of a typical turbine-driven generator.

A large a-c propulsion motor is illustrated in Figure 14 with the path of the ventilating air indicated by the arrows. At the left can be seen the built-in cooler and propeller-type blowers. A similar type of ventilating scheme for a propulsion motor is shown in Figure 15 except centrifugal-type blowers are used instead of propeller type.

Auxiliary equipment on shipboard is often located in such a manner that serious limitations are imposed on ventilation. Motors must have enclosures varying from drip-proof and splashproof to totally enclosed. Auxiliary motors must sometimes be placed in locations where they are subjected to very oily atmospheric conditions so that nothing short of totally enclosing the motor will prevent undue maintenance. Obviously it would be impractical to have separate ventilating systems for small auxiliaries such as

Figure 16. D-c compressor motor with drip-proof covers

Figure 18. Totally enclosed fan cooled motor

have been described here for propulsion equipment and larger auxiliaries. In small sizes these auxiliary motors are under rated and built totally enclosed without any separate ventilation, depending only on the external exposed surface to dissipate the losses. There is a very definite limitation on the size of the motor which can be built in this manner. This is because the rating and losses vary approximately with the square of the diameter whereas the surface increases only as the first power of the diameter. Increased output can be obtained by adding external fins thus increasing the radiating surface. The limit can be extended still farther by the use of the so-called fan-cooled type of motor. This motor is designed with fins on the inside surfaces and an internal fan to give the best possible heat transfer from the active material to the heat conducting surfaces. An external shaft mounted fan blows air over the external fins instead of depending only on the natural radiation.

It is in this field, where machines have a very high degree of enclosure, that the use of silicone insulation will prove to be of maximum value. This is because the temperature limitation is reached long before any such limitation as efficiency, pull-out torque, commutation, and so forth, is reached.

Figures 16, 17, and 18 show auxiliary marine equipment with varying degrees of enclosure. Figure 16 is a compressor motor with drip-proof covers. Figure 17 is a drip-proof semienclosed pump motor. Figure 18 illustrates a totally enclosed fan-cooled motor.

In conclusion it may be stated that installations of electric equipment on shipboard make it necessary to provide machines with varying degrees of enclosures. The location of the machinery imposes also certain restrictions on the ventilation system. Due to the temperature limitations of insulation, these machines must be cooled or ventilated and it is the problem of the designer and application engineer to do this with the most economical use of space and material. In some cases it may simply mean supplying machines with the correct enclosure to protect the machine properly. Specifications should never call for a degree of enclosure more than is absolutely necessary, as any restriction in ventilation will reduce the output obtainable from a given machine.

Discussion

W. H. Fifer (Navy Department, Washington, D. C.): Proper ventilation of rotating electric equipment on shipboard not only depends on proper design of the equipment itself but is also equally dependent on proper installation. Installation features requiring close attention on naval vessels are as follows:

1. Naval vessels must be capable of operating in the tropics under darkened ship conditions which greatly increases the ventilating problems. Machinery space ventilating systems must be designed which are capable of maintaining an ambient temperature which is within the maximum ambient temperature for which the electric equipment is designed.

2. When open rotating electric machinery is used, the ventilation problem is greatly aggravated due to the large amount of heat given out by the machine. For example, an installation composed of two 1,000-kw generators supplying power to two propulsion motors of equal size would dissipate a total of 240 kw, assuming the efficiency of the motors and generators to be 94 per cent. When this heat is added to the heat losses of the Diesel engines and other equipment in the machinery spaces, it becomes a very difficult problem to supply sufficient air to maintain the ambient within practicable limits.

3. The ventilation problems for machinery spaces of Diesel-driven vessels is further aggravated by the requirement for engine intake air. Since most of the engine manufacturers object to using hot air for the engine induction, the engines require a large amount of the cool air from the machinery space ventilation inlets. This greatly increases the total amount of inlet air required.

4. Another installation problem requiring close attention with open machines is the recirculation of the air within the machinery spaces. For example, electric machinery located adjacent to other equipment may draw its inlet air from the hot discharge of the adjacent equipment. Also, baffles are frequently required to be placed under the foundations of open electric equipment to prevent sucking its own hot discharge air back into its inlet.

5. Another problem which has given considerable difficulty on naval vessels is the distance from the bilges which must be maintained to prevent water from splashing into or entering open machines. On naval vessels, where open machines must be located close to the bilges, the lower half of the machines are enclosed in watertight casings which makes the ventilation problems within the machine more difficult.

6. It is noted from Figure 9 of Harrison's paper that some installations are made with suction-type ventilation attached directly to the machines. It has been found that this method is not practicable for use on naval vessels, since either extremely adverse conditions of weather or untrained personnel forcing water into the topside inlets when washing down the decks with hoses has invariably resulted in salt water finding its way into the electric machinery.

7. Experience on naval vessels has indicated that use of the double-tube-type of air coolers is the only practicable way of keeping salt water from getting into electric equipment fitted with air coolers. With the higher temperatures being used with present-day machines and insulating materials, a leak from a single tube cooler will almost immediately vaporize and carry salt through the entire system.

8. As noted from Figure 13 of Harrison's paper, a considerable amount of air can be made to flow through the cylindrical rotor of an a-c turbine generator. Unless a recirculating system using an air cooler is employed with this method, oil vapor from the machinery space will soon contaminate the windings of the rotor.

Experience obtained from the construction and operation of over 1,000 electrically propelled vessels during the past war has definitely indicated that the only satisfactory method for ventilating large rotating electrical machinery is by the use of the recirculating systems employing double-tube air coolers.

The additional initial cost of this type of equipment is far more than off-set by the reduction in maintenance of the equipment and the additional cost of supplying adequate machinery space ventilating systems for use with open machines.

J. F. Sellers (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): This paper by Harrison gives a very good description of the experience gained in the large-scale application of d-c machines on shipboard during the war. Except for auxiliary d-c motors, most of the applications did not involve severe commutating problems because of the overloading limitations of the prime movers, such as Diesel engines and turbines. The use of silicone insulation, especially in larger machines, had not progressed to the point where commutation and mechanical problems became the limitations. Thus, the problem on d-c machines was to concentrate on ventilation methods to obtain the greatest output from each machine, consistent with good insulation, brush, and commutator reliability.

The use of either axial air ducts or radial ducts can be decided by direct comparison with the same armature size, and it also may be decided by the application. Axial ducts are used usually where blowers are available, and where coil insulation must be protected from large amounts of dirt, especially abrasive dirt.

Reduction of the bad effects of carbon dust on insulation resistance by the flow of cooling air from the back of the machine to the commutator end was generally recognized, even though it resulted in somewhat

higher operating temperature for the commutator and brushes. For 40-degree centigrade rise machines the temperature effect on the brushes was not noticeable, but, for 70-degree centrigrade rise and silicone machines, the increasing commutation and brush problems with each higher ten degrees (centigrade) came to the front. This situation has led to the study of a ventilation system which will keep the carbon dust out of the machine windings, and still give the coolest air possible to the commutator and brushes. It is our opinion that the full use of silicone insulation and such a ventilating system in the future will give such an increased output per pound of active material (in machines of larger size) that considerable research and improvement will be needed in commutation adjustment and the mechanical design of commutator, brush, and brush holders.

Shipboard Degaussing Installations for Protection Against Magnetic Mines

NICHOLAS B. MICHEL
NONMEMBER AIEE

EARLY in World War II the German navy and air force started to lay a new type of sea mine, reputed later to be the first of the "secret weapons." This mine was detonated at a distance beneath a ship by the ship's influence rather than by actual contact as was necessary for previous types of mines. Due to the mystery surrounding the means of operation of this mine and the lack of countermeasures, it was a threat to Allied shipping.

This was the situation when one night in November 1939 German planes were observed to release strange ground mines with parachute attachments which fell into shallow water off the English coast Several of these mines were recovered by British mine officers and successfully dismantled. Upon removal of the mine dome, a manual latitude adjustment was revealed labelled "Gauss" which immediately confirmed suspicions that the new weapon was a magnetically-operated mine.

Further examination proved this correct since the sensitive firing mechanism included as the actuating element a magnetized needle mounted so as to complete an electric circuit upon a predetermined swing of the needle. This initiated detonation of the mine. It was found that the distortion caused in the earth's field by the passage of a steel ship was being used to upset the balance of a magnetized needle in the mine causing it to detonate beneath the ship.

As a result of the use of this mine the United States Navy set forth on an extensive program of reducing the magnetic field of its ships by the use of demagnetizing or "degaussing" coils. This program involved fitting approximately 12,000 naval and merchant ships with coil installations, which along with the minesweeping program were successful during the war in affording such protection that the losses from this type of mine suffered by our ships were small.

The Problem and Solution

The problem of protection of ships against magnetic mines offered only one solution, other than that of sweeping the mines, and that was to reduce the magnetic effect of the ship on the mine so as not to swing the mine magnetic needle to the contacts. This process became known as "degaussing."

Degaussing took two main forms. The first of these consists of temporarily wrapping a coil of heavy cables around the outside of the ship, either in a horizontal plane encircling the hull at about the waterline, or in solenoid fashion about the centerline of the vessel with cable loops in vertical planes encircling the vessel from weather deck and superstructure to keel with the loops perpendicular to the centerline. Controlled direct current in definite schedules of pulses passed through the temporary cables produces strong magnetic fields which reduce the original magnetic field of the vessel. This type of degaussing is known as "magnetic treatment" and is temporary in nature since after the coils are removed and the ship operates in the earth's field, the effect of the treatment decays. This treatment is done by especially equipped "degaussing stations."

The second type of degaussing consists of installing permanent coils on the ship which when energized with direct current set up a magnetic field that opposes the ship's magnetic field and thereby reduces the change in the earth's field beneath the ship. This type is known as a "shipboard degaussing installation" and is the main subject discussed by this paper.

The Earth's Field

The magnetic field of the earth can be represented as shown by Figure 1 with flux lines leaving the earth's magnetic South Pole and entering at the magnetic North Pole. The field surrounds the earth at all points and for small regions can be assumed to be of uniform strength. If the field is considered at some point A on the surface of the earth, the field can be imagined to exist as shown by Figure 2. If a steel ship now steams by point A, the distortion shown by Figure 3 results. Since a magnetized needle in a magnetic mine tends to line up with the lines of flux, it is evident that rotation of the needle would result as the ship steams over the mine, momentarily bending the lines of flux from their normal positions.

For purposes of degaussing it is convenient to resolve the earth's field into its vertical and horizontal components (Figure 4) and to treat the effects of each component on the ship separately.

From consideration of Figures 1 and 4 it can be observed that the earth's horizontal component is always from south to north while the vertical component is upward in the southern hemisphere and downward in the northern. Further, the strength in milligauss of the two components varies with the latitude. The horizontal component reaches a maximum of 410 milligauss at the magnetic equator and becomes zero at the poles, while the vertical component reaches a maximum of over 650 milligauss at the poles and is zero at the magnetic equator.

The Ship's Field

The distortion of the earth's field caused by the presence of the ship in

Paper 48-227, recommended by the AIEE marine transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted July 22, 1948; made available for printing August 27, 1948.

NICHOLAS B. MICHEL is with the Bureau of Ships, Navy Department, Washington, D. C.

Figure 1. The magnetic field of the earth

Figure 4. Vertical and horizontal components of the earth's field

Figure 3 can best be analyzed by subtracting the uniform field of the earth from the distorted field and thus obtain the field of the ship. The field of the ship can then be considered the disturbing field and conveniently resolved into horizontal and vertical components. Since the horizontal component may have any angle with respect to the centerline of the ship because of the ship's ability to change heading, it is found desirable to resolve this component further into a longitudinal component along the direction of the vessel's centerline and an athwartship component perpendicular to the centerline. The ship's field then consists of three mutually perpendicular components: vertical, longitudinal, and athwartship.

Each of these components is due to two types of magnetism, so they must be further broken down. The first type is the induced magnetism which accounts for most of the ship's field. This type is the magnetism induced in the steel and retained only while the ship is in the presence of the earth's inducing field. The second type is the permanent magnetism which is taken on by the ship's steel while being mechanically worked in the presence of the earth's field and which is retained until decayed and not dependent for its existence on the immediate earth's field conditions.

Therefore, in considering all the possible components of the ship's field which might add up to give enough magnetism to detonate the mine we would list for completeness:

Vertical	Horizontal
Induced	Induced longitudinal
Permanent	Permanent longitudinal
	Induced athwartship
	Permanent athwartship

The polarity of the vertical induced will be upward in the southern magnetic hemisphere and downward in the northern. The direction of the horizontal induced will remain from magnetic south to north regardless of the heading of the vessel. The polarities of the permanent longitudinal and permanent athwartship magnetism will be fixed over long periods with regard to direction on the ship and will be independent of heading.

The magnitude of the induced vertical component will vary directly as the variation of the earth's inducing vertical field component from a maximum at the magnetic poles to zero at the magnetic equator. The magnitudes of the induced longitudinal and athwartship magnetisms will be a function of the ship's magnetic heading as well as the strength of the earth's horizontal inducing field component.

Therefore the ship's field is a complex affair which depends on the following conditions: past magnetic history; immediate magnetic heading; and immediate latitude position.

The Degaussing Coil System

In order to obtain a degaussing coil system having its runs parallel to decks and bulkheads and permitting simple control of currents for latitude and heading changes, the degaussing coils are each designed to neutralize either specific vertical or horizontal effects so that the complete coil system would take care of all effects.

The degaussing coils and the effects they neutralize are as follows:

M-Coil. This coil encircles the ship just inside the skin of the hull in a horizontal plane approximately at the water line. This coil is shown by Figure 5. The M-coil neutralizes the sum of the induced vertical and permanent vertical magnetizations by superimposing on the ship's field a coil field having approximately an equal and opposite effect beneath the ship.

F- and Q-Coils. These coils are located at opposite ends of the vessel in horizontal planes and connected in series. The F-coil encircles the forward one-third or one-fourth of the ship and is located just beneath the forecastle or uppermost deck. The Q-coil encircles the after one-third or one-fourth of the ship and is located just beneath the quarter deck or uppermost deck. These coils are shown by Figure 6. The F- and Q-coils are connected in series with each other so as to have polarities in

Figure 2. The magnetic field at the surface of the earth

Figure 3. Distortion of the earth's field caused by presence of a ship

Figure 5. M-coil

Figure 6. F- and Q-coils

Figure 7. Neutralization of the ship's longitudinal magnetism by the use of F- and Q-coils

opposite directions. The F- and Q-coils develop strong fields below the bow and stern of the ship to approximately neutralize the sum of the induced and permanent longitudinal magnetism in these regions as shown by Figure 7.

L-Coil. In cases where a better matching of the ship's field is required than is afforded by the F- and Q-coils, an L-coil is installed in lieu of the F- and Q-coils. However, due to the increased difficulty of installing an L-coil, its installation is uncommon. The L-coil is a solenoid with its axis parallel to the axis of the ship's field being neutralized by it, thereby obtaining a better match. The L-coil is composed of a series of loops in vertical planes perpendicular to the centerline of the ship. The loops each run inside of the hull from the keel to the underside of the weather deck as shown by Figure 8. The loops are all connected in series to form the L-coil.

A-Coil. This coil runs with loops vertical in fore and aft planes running from the inside of the ship's inner bottom to the underside of the weather deck as shown by Figure 9. This coil usually consists of two loops. One loop runs the full length of the ship, while the second loop runs in the central portion of the vessel only to give added magnetic strength in this section. In the central portion of the vessel the loops are located outboard of the centerline, while the portions of the loop fore and aft of this are on the centerline. The A-coil neutralizes the sum of the induced and permanent athwartship magnetisms.

The Degaussing Cable Installation

The first degaussing installations made were in desperate haste and utilized the equipment immediately on hand at the shipyards. It was not fully appreciated that degaussing coils placed within the hull could effectively give protection. Therefore, the first installations were made with the cable clamped outside of the hull, encircling the ship at levels varying from about ten feet above the waterline to the weather deck level. Other early installations were made in the waterways of the weather deck just within the bulkwarks. At this time M-, F-, and Q-coils only were used. The cables for these installations were made in the yard by bundling together conductors of American Wire gauge number 2 rubber covered wire, tightly wrapping with canvas tape and sewing a tightly fitting canvas cover over the entire length of cable. Control of the ampere turn strength of these coils was obtained by switching turns in and out of the circuit, the coil being fed from the ship's 120-volt d-c ship's service bus.

It was quickly evident that this type of installation was not practical since the terrific force of the sea on the cables, which were up to about five inches in diameter and racked three and four cables together, tore them loose in spite of heavy straps and steel plate guards. Also, if this did not occur within a few voyages, the cables became water soaked and the conductors grounded out. The switching method of control was not satisfactory because of the coarseness of the steps.

However, in the meantime, electrical cable, rheostat, and motor generator manufacturers were rushing to completion more suitable equipment ordered by the Navy. This later equipment did prove satisfactory and was used throughout the war in the degaussing of some 12,000 naval and merchant vessels.

Based on the experience of the early installations, the subsequent ones, with few exceptions, were placed inside of the vessels. Due to the shielding effect of the steel hull and reduction of core effect, the magnetic efficiency was reduced by approximately 30 per cent, but the reduction in maintenance on the coils more than justified this move.

The prefabricated cables were of two general types for naval vessels, single and multiconductor. The single conductor cables were designed for use with low-voltage motor-generator sets on large combatant ships and the multiconductor for use in series with rheostats and supplied from the 120 or 240 d-c ship's service on the smaller combatant vessels and auxiliaries. For the merchant marine installations a larger multiconductor cable was similarly used with rheostats and supplied from the ship's service of 240-volt direct current.

Figure 8. L-coil

Figure 9. A-coil

The type of cable construction used on the naval installations followed the pattern of the standard Navy heat- and flame-resistant cable except that the insulation thickness was reduced in order to save critical material. This reduction was permissible due to the lower operating voltages of the degaussing coils. The most common type of single conductor cable was used in conductor sizes ranging from 400,000 to 2,000,000 circular mil areas. The conductor was insulated with felted asbestos and varnished cambric tapes, covered with an impervious nonmetallic sheath and over this a braided metal armor.

The multiconductor cable was used as a 19-conductor cable with conductor sizes ranging from 6,000 to 40,000 circular mil area. Each conductor was insulated with felted asbestos and varnished cambric tapes and an identifying braid. The assembly was held by a binder and covered with an impervious nonmetallic sheath and braided metal armor.

The outside diameter of both these types ranged from $1^1/_4$ to $2^1/_4$ inches. When it is considered that on some installations the number of these cables in the wire ways ran as high as eight to ten cables, an idea may be had of the large size of the cable runs.

On many ships the strength of portions of the main degaussing loops are changed by short loops at the level of the main loop which are connected in series with the main loop. The function of these short loops is to take care of peaks in the ship's field.

On most ships the cable runs are made on the inboard edge of the frames or through lightening holes in the frames. When a tank occurs in the way of a run that would necessitate a large deviation to jog around, the tank is pierced with a conduit for each cable. Similarly cables are run through refrigerated spaces when necessary in order to avoid large deviations.

In running degaussing cable aboard ship one unfortunate requirement that continually causes despair at the installing activities and sometimes creates bad maintenance conditions is that the location of the cable runs must be closely dictated by the magnetic design of the coil rather than by selection for ease of installation. As a result the cables many times must run through crowded or wet compartments in which relocating of equipment, piercing of closely spaced bulkheads, making of many small deviations, correction of interference with piping and so on, must be accomplished to permit the run to be made, while nearby a completely clear passageway may exist but just beyond the limits of allowable deviation for the run.

Many runs have to be made in water and oil-filled bilges. For these runs experience has shown lead covered cable to be the best solution. Earlier installations in bilges using watertight conduit were a source of trouble due to leaks developing in the conduit and eventually causing the cable to become grounded.

One type of vessel on which a complete internal degaussing installation was not found advisable was tankers. On these vessels the cargo tanks were too extensive to permit the running of cables inside the hull in conduit both from the structural and fire hazard standpoints. The cable run on these ships was made at the level of the weather deck in order to get over the cargo tanks. In the forward and after ends and at midship where deck houses cover the weather deck, the run was made inside of the deck houses just above the deck. The remainder of the run was made on the weather deck using a special cable mounted on saddles several inches off the deck and just inside of the bulkwark. Heavy steel plate guards were mounted over those portions of the run exposed to mechanical damage. These guards were designed to present sloping surfaces to the wash of the sea to prevent their being torn loose. The first type of cable used for the exposed portions of the tanker installations consisted of a multiconductor lead sheathed cable covered with jute, heavy wire armor and jute outer covering. This type cable installation was successful for about nine months after installation when the cable on numerous tankers started to ground out. Investigation revealed minute transverse cracks along the lead-sheath due to fatigue of the lead. This fatigue was due to the continual stressing of the sheath caused by vibration of the hull.

As a result of these failures an improved type of cable was developed for this service covered with a nonmetallic sheath, duck tape, and heavy steel tape armor. In this cable the resiliency of the sheath has corrected the previous trouble.

Control Equipment and Power Supplies

In installations using multiconductor cables, the coils are formed by connecting the conductors of the cables in series to obtain the desired number of turns. On the basis of the number of turns available, operating currents for the various magnetic latitude zones and heading are specified by degaussing stations where the ship's field is measured by sailing over a row of submerged magnetic detectors known as a degaussing range. The required currents are set by the ship's force by means of manual or motor operated rheostats. Figure 10 illustrates the control system of a typical degaussing installation of M-, F-, and Q-coils in which the F- and Q-coils are composed of multiconductor cable and the M-coil of single conductor cable. An A-coil was not used here because the degree of protection desired did not require it; however, the controls would have been similar to the FI-QI coil. In this figure a common arrangement of splitting the F and Q coils into separate FI-QI and FP-QP circuits is shown. The FI-QI circuit neutralizes induced longitudinal magnetism only while the FP-QP circuit takes care of permanent longitudinal. Polarity of the currents in the FI-QI and FP-QP coils is adjusted by means of the reversing switches.

In the single conductor M-coil, power is supplied from a low-voltage motor-generator set. Output current and polarity of the generator are adjusted by means of a motor operated rheostat wired to permit reversing the generator field current. In many installations the motors for the motor-generator sets are supplied from the ship's service 440-volt a-c bus instead of as shown by Figure 10 which applies to a d-c powered ship. On smaller ships the coils are all composed of multiconductor cable and controlled by rheostats. On larger ships all coils are single conductor or the M-coil single conductor and the other coils multiconductor as shown by Figure 10. The choice of single conductor cable instead of multiconductor is made when the length and ampere turn capacity are so great that the number of multiconductor cables required would be excessive.

Connections to control equipment and between cable sections are made in watertight connection boxes on terminal strips with solderless-type connectors. These connection boxes facilitate adjustment of turns by degaussing stations in order to obtain the best degaussing and permit isolation of grounded conductors. However, some trouble has been experienced due to flooding and condensation in these boxes. The solution to this problem has been in filling of the boxes with a removable polymerizing plastic compound which completely seals the box against moisture. This plastic can be removed if necessary by digging out with hand tools.

Power Requirements

Different classes of ships receive different degrees of degaussing protection de-

pending on their undegaussed field and expected duties. This means that wooden hull and small vessels would receive an M-coil only, larger vessels M, F and Q and best degaussed vessels M, F, Q, and A. The degree of protection established as the desirable standard for each type of vessel must take into account the practical aspects of the installation that would be required to meet this standard. It is necessary to follow this policy rather than to attempt to obtain the best possible degaussing for all vessels since the degree of protection obtained for the amount of effort and material expended follows a law of diminishing returns.

Perfection in degaussing by eliminating all of the ship's field is not attempted on any ship due to the physical impracticability of such an installation. However, the mine target area beneath the ships is reduced to such an extent that when coordinated with the minesweeping program, reasonable safety is obtained.

Based on these considerations the power requirements on typical representative classes of ships are listed in Table I.

Figure 10. Typical wiring diagram for degaussing installation with M-, F-, and Q-coils using both single and multiconductor cable

Effect on Other Equipment

Since the degaussing coils must produce fields extending rather long distances, the strength of the coil fields in the immediate vicinity of the cables is sufficiently high under some conditions to adversely affect operation of other equipment. For example, this magnetic field will be about two gauss in a compartment at a distance of five feet from a degaussing coil producing 1,500 ampere turns. Closer to the degaussing cable much stronger fields will be encountered, while throughout the vessel at distances ten or more feet from the degaussing cable, magnetic fields of about one-half to one gauss may be expected. These fields will add vectorally to the earth's field in the vessel, which in navigable waters would be up to about 0.6 gauss, to produce a resultant field which may affect electric welding operations, magnetic and gyro compasses, electrical measuring instruments, radar cathode ray tubes and other similar equipment unless preventive measures are taken. The preventive measures take three forms: relocation of affected equipment away from degaussing coils; installation of shields on affected equipment; installation of compensating coils fed from the degaussing coil circuit.

Of these effects the most common is the deviation effect that would be caused on the magnetic compass by the degaussing coil fields. In order to eliminate this deviation effect, prefabricated compass compensating coil assemblies are mounted on the binnacles and fed from a voltage tapped off of the disturbing degaussing coil circuit. By means of adjusting resistors, the current in the compass compensating coils is set to neutralize the effect of the degaussing coil on the compass needles. Once this adjustment is made, the compensating current will vary as the degaussing current and automatically produce correct compensation for all degaussing currents.

Degaussing coils may interfere with electric arc welding if the field at the arc approaches a strength of about 70 gauss. Under this condition noticeable irregularities in the welding operation will occur. Steel-backing plates rigged across the joint being welded will sometimes correct this effect by reducing the field in the event the degaussing coils cannot safely be secured.

In other cases of interference, local shields on the equipment have proved satisfactory in the event that neither the equipment nor the degaussing coil could be relocated.

Table I

	Kilowatt Demand Load	Feet of Cable Used
Battleship	100	12,500
Aircraft carrier	75	15,000
Cruiser	75	9,000
Destroyer	15	2,500
Patrol vessel	3	900
Merchant vessel (Liberty Ship)	20	2,200

Conclusions

Degaussing for protection of ships against magnetic mines has proved to be practical both from the standpoint of installation and operation. While it only gives a partial and negative type of protection, its value can be realized by the rate of casualties which occurred at the beginning of the War when the magnetic mine was introduced by the Germans. Had the enemy withheld the use of the magnetic mine until it could have been first laid in very large quantities, it would have been highly successful due to the lack of available countermeasures. As it was, the Germans laid about 8,000 magnetic mines the first year and increased

the rate to 12,000 or 18,000 in the second year.

By the third year the rate decreased sharply due to the diverting of most of the aircraft groups, which laid the majority of the mines, to the Russian campaign. Also, the early mines were of a 50 milligauss type which was a comparatively low sensitivity. Protection by degaussing against this low-sensitivity mine was easier to obtain than if a high-sensitivity mine had been used since the fitting of the coils was not as critical. This fact aided the cause of degaussing by permitting it to get established before the requirements were tightened up by the use of more and more sensitive mines. The enemy was forced into the use of these more sensitive mines by the fact that degaussing reduced the possibility of the insensitive mines being detonated by the degaussed ships. This development, however, has an advantage in the fact that the more sensitive mines may be swept over larger areas and depths at every pass by the minesweepers.

At the present time the degaussing installations on all naval vessels are being maintained and have become a permanent part of the vessels' electric equipment. In some parts of the world these vessels are still required to operate their degaussing installations due to the existence of magnetic mines which have remained unswept and which may still be dangerous to navigation.

Discussion

A. Solem (Navy Department, Washington, D. C.): For an effective degaussing program, the ships' degaussing coils must be used properly and the ships must be in standardized magnetic states which these coil systems can degauss. After degaussing coils have been installed, each ship visits a degaussing station to be degaussed to the limits required by the general program. At the degaussing station, the ship's magnetic fields are measured; if necessary, the ship is depermed; and the ship's degaussing coils are calibrated. Deperming is the magnetic treatment which alters the ship's magnetic state so that its degaussing coils will satisfactorily degauss the ship. Degaussing calibration consists of determining and transmitting to the ship the proper degaussing coil currents needed to minimize the ship's external fields. Further degaussing action for the ship, aside from using the coils as instructed, is an occasional checking of the ship's degaussed condition and new depermings and calibrations as is found necessary.

Degaussing Stations

Degaussing stations are made up of deperming facilities where depermings and calibrations are performed, and channel ranges where periodic checkings and general calibrations are performed. The size of the degaussing station varies with its location and the type of ships it handles. A large station may have several ranges and deperming facilities; a small station may consist of only a single channel range.

Deperming Facilities. The deperming facility is located, if possible, at some quiet but easily accessible spot within the harbor which the degaussing station serves. It usually consists of a magnetometer garden fixed in the harbor bottom adjacent to a pier, where the magnetometer controls and deperming power supply are located. A facility for small ships will have approximately 50 detectors spaced about 20 feet apart at a 30- to 40-foot depth, spread out to give a complete survey of fields in the area alongside the pier. A facility for large ships will have up to 75 such detectors spaced approximately 40 feet apart at a 60- to 70-foot depth in the survey area. The detectors are set in copper pipes jetted into the bottom; hence, their depth is not limited by harbor depth. Some gardens have two depths to handle all sizes of ships.

Measurements at the deperming facility are made with the ship moored directly over the detectors. The ship's signature or field consists of the magnetic-field values at a series of points spread out on a horizontal plane beneath the ship. The necessary longitudinal and athwartship profiles and the contours of the ship's over-all field can be constructed from these point values.

When the installation of an elaborate magnetometer garden is not warranted, it is sometimes possible to measure the ship's fields with portable magnetometers. With the ship at anchor, the magnetometer is suspended in turn at various points along the ship's length, and a field measurement is obtained at each point. These measurements are then used to construct the signature. The magnetometer must hang freely beneath the ship, and the harbor depth, unless it is very deep, limits the use of portable magnetometers.

Channel Ranges. The channel range is located in a ship channel where all ships may use it. The range detectors (range coils) are located in the channel bottom on a line perpendicular to the direction of ship passage through the channel. A range for small ships will have approximately 20 detectors spaced 10 to 20 feet apart at a water depth of 30 to 40 feet. A range for large ships will have approximately 30 detectors spaced 20 to 40 feet apart at a depth of 50 to 75 feet. Here also, the detectors are attached to piling or set into copper pipes jetted into the channel bottom, and their depth is not limited by channel depth. A range house overlooking the channel contains the recording instruments (fluxmeters), and serves as the control station governing movements of ships on the range.

As the ship passages over the range the fluxmeters make continuous records of the magnetic field at each detector. Each passage of the ship over the range produces a series of equally spaced longitudinal traces of the ship's magnetic field which comprise the ship's signature. The traces may be used independently or the data from them may be used to draw contours of the ship's signature.

Some less elaborate ranges use a long narrow loop stretched across the channel as the detector. The loop is about 500 feet long and 10 feet wide. It lies on the channel bottom, and its depth must be the same as the channel depth. This type of range does not give magnetic field measurements as a series of longitudinal traces, but does give the magnetic flux changes produced by the ship which can be used to check the condition of ships.

The detectors of the deperming facilities and the channel ranges are oriented to measure the vertical component of magnetic field. Undue complications would result if total field measurements were required (simultaneous measurement of three mutually perpendicular components would be needed), and the instrumentation is easier for the vertical component than for one of the horizontal components. The vertical field components are also larger than the horizontal components, and hence give clearer pictures of the degaussed condition of the ship. Whenever possible the channel ranges and deperming facilities are located such that the ship's fields are measured on north-south heading.

Deperming

Ships are depermed to standardize their magnetic states. Ideally, the postdepermed state has zero PLM and PAM, and a $PVM + IVM$ in magnetic equilibrium with the earth's vertical field.* The deperming process consists of mooring the ship at the deperming pier, wrapping it with the deperming-solenoid shaking coil, and then shaking it magnetically with a series of d-c pulses in the solenoid. These current pulses, furnished by a large number of storage batteries in a series-parallel connection, are of alternate polarity. High currents are used initially with the current values diminishing through the schedule. Thus the ship's steel is carried through a demagnetization schedule of diminishing hysteresis loops. The horizontal component of the earth's field is balanced out by a compensating coil during treatment to produce the demagnetization of LM and AM. Since the vertical component of the earth's field is present during treatment, the shaking schedule increases PVM to a maximum value so the total VM is in equilibrium.

Deperming of a ship has to be repeated whenever the vessel develops excessive PLM or PAM, or irregular VM. Some vessels require redeperming within a few

* The following technical abbreviations have been used in this discussion:

VM—vertical magnetization
LM—longitudinal magnetization
AM—athwartship magnetization

IVM—induced vertical magnetization
ILM—induced longitudinal magnetization
IAM—induced athwartship magnetization

PVM—permanent vertical magnetization
PLM—permanent longitudinal magnetization
PAM—permanent athwartship magnetization

months of a previous treatment; others may never require retreatment. When a ship will require retreatment is unpredictable, and practical scheduling of deperming is possible only with frequent checking of the degaussing of all ships.

Calibration

Procedure. Calibration of the ship's degaussing system may be performed on either the channel range or the magnetometer garden. Ships depermed are ordinarily calibrated on the magnetometer garden at completion of the deperming; all others are calibrated on the range. Calibration procedure on a north-south channel range is as follows:

1. The ship's undegaussed signature is obtained on two passes of opposite headings across the range.

2. The M-coil is energized and the current in it adjusted on successive runs across the range until the residual field under the middle third of the ship is reduced to a minimum. The M-coil compensates *VM*, and its current will be the same on both headings.

3. With the M-coil set at best current the FI-QI or L-coil is energized and the current in it adjusted such that a given positive current on north heading and a negative current of the same magnitude on south heading produce uncompensated residuals of the same shape and magnitude on both north and south headings. The FI-QI or L-coil compensates *ILM*. Its current has the same magnitude on north and south headings but opposite polarities.

4. With the M and FI-QI coil currents adjusted to proper values the FP-QP coil is adjusted to reduce the remaining misfits at bow and stern. This may be an adjustment of both currents and loop turns. The FP-QP coil compensates *PLM* and M-coil misfit, and its current will be the same on both headings.

5. If the ship has an A-coil, the A-coil current is adjusted to remove any athwartship asymmetry of the signature. This is *PAM* compensation. *IAM* compensation will be accomplished by measurements with portable magnetometers when the ship is moored on east-west heading.

Ordinarily a calibration does not require all the steps indicated since only one or so coils require changing. Statistical values of the FI-QI and A currents are used also to shorten the procedure. Often a calibration can be effected in one or two runs.

Calibration procedure on the magnetic garden is similar except that all possible adjustments of currents are made while the ship is on one heading; the ship is then swung to the opposite heading and the current values are checked for validity.

Degaussing Charts. The degaussing current settings are transmitted to the ship on degaussing current setting charts. Each coil is given a set of currents valid for worldwide operation. The M-coil current varies with variation of the earth's vertical field, but not in direct proportion because of the presence of *P VM*. M-coil currents are positive in the northern hemisphere, tending toward zero at the equator, and becoming negative in the southern hemisphere. The FI-QI- or L- and A-coil currents vary directly with the earth's horizontal field. They are maximum at the equator and decrease both north and south of the equator. In addition the FI-QI current varies as the cosine, and the A current varies as the sine of the heading angle. The FP-QP varies with location if it compensates M-coil misfit, and it is constant if it compensates *PLM*. The calibration determines the setting constant for the M- and FP-QP coils, and the proportionality constant for the FI-QI and A-coils. The variation of the M-coil current with location is determined statistically from data on many ships.

Changing of current with change of heading or location is not continuous, but occurs in steps. This relieves the ship of keeping a continuous degaussing watch, and permits degaussing duties to be combined with some other duty.

Check Ranging. Check ranging requires that the ship pass over the range having its degaussing coils energized with the current settings given at time of last calibration.

At completion of the check the ship is informed of its condition and corrective action needed, if any. The ship then makes arrangements with the degaussing station to complete the action.

E. Peizer (Navy Department, Washington, D. C.): I wish to outline some of the main features of the instruments used in the methods of measurement of ships' fields outlined in the previous discussion. These methods were: coil ranges, loop ranges, fixed magnetometer proving grounds, and portable magnetometers.

Coil Ranges

For coil ranges the basic equipment consists of fluxmeters with associated control gear in the range house electrically connected to a line of detector coils at the sea bottom. Measurements of a ship's field are recorded by a pen on a strip-chart in the fluxmeter when the ship passes over the line of coils.

The principle of measurement of magnetic field by a fluxmeter-detector coil combination is as follows:

1. A fluxmeter is essentially a d'Arsonval-type moving-coil galvanometer in which the suspension restoring torque has been effectively removed or cancelled out. The moving-coil of the galvanometer is connected to a detector coil at the location where the measurement of field is desired.

2. If the magnetic flux through the detector coil changes, an electromotive force is generated producing a current through the circuit.

3. This current passing through the galvanometer moving-coil rotates the moving-coil in the field of the galvanometer pole pieces in the direction which introduces flux linkages into the circuit of opposite polarity to those introduced at the detector coil, thus tending to reduce the net flux change in the circuit.

4. If the galvanometer moving-coil is sufficiently responsive it will move at all times in such manner as to limit the net flux change in the circuit to a negligible value.

5. For a uniform field at the moving-coil, the deflection of the moving-coil from its initial position will be proportional to the change in flux through detector coil from its initial value.

6. The fluxmeter deflections are thus proportional to the change in average field intensity over the cross-sectional area of the detector coil. For the detector coils used at ranges the variation of the field from the average value is of no significance.

The fluxmeter in use by United States Navy channel ranges has a sensitivity of about 300,000 flux linkages (centimeter-gram-second units) for full scale deflection. This instrument was originally developed by the General Electric Company in 1941. A standard taut-suspension type, moving-coil galvanometer was modified to serve as a fluxmeter. The restoring torque due to the suspension was balanced out by means of a magnetized needle (magnetic dipole) mounted on the suspension and positioned between a pair of soft iron plates whose spacing was adjustable. The soft iron plates concentrated the stray field of the pole pieces of the galvanometer and produced a relatively uniform field at the dipole whose intensity could be varied by adjustment of the plate spacing. With the dipole suitably oriented, the torque on the dipole due to the field was proportional to the sine of the angle of displacement from the position of zero suspension torque and directed outward from this position. For small angles the torque on the dipole thus approximately compensated the restoring torque of the suspension. In addition to the restoring torque of the suspension which was symmetric about the zero position, an asymmetric torque was noted. This torque was largely compensated by means of a rotatable ring containing a piece of soft iron which concentrated additional field between the pair of plates.

One of the main difficulties encountered in the operation of the fluxmeters at degaussing ranges was the tendency of the meter to drift when no ships were passing, that is, when no signal was being applied at the detector coil. This drift originated primarily from thermal junction electromotive forces in the fluxmeter and from sea battery electromotive forces in the underwater installation. Manual drift control was relied upon at first. Later an automatic drift control was developed which considerably simplified the operation of the ranges.

The detector coils used in coil ranges were normally mounted with axis vertical for measurement of the change in vertical component of field. Air core coils were first used which consisted of a number of turns of multiconductor cable wound on a circular frame about five feet in diameter. These coils were replaced by coils with high permeability cores (Permalloy or Mumetal) which are now standard. Sensitivities of the order of 10,000 flux linkages (centimeter-gram-second) per milligauss were used. Introduction of the high permeability core permitted design of a much more compact coil using a large number of turns of fine wire.

These coils were generally mounted at the sea bottom either by suspension in pipes driven vertically into the sea bottom, or by gimbal mounting in an outer case which was mounted on a tripod.

Loop Ranges

Loop range equipment operates on the same general principles as that of a coil range. The main difference is that a loop of multiconductor cable about ten feet wide and several hundred feet long is used for collection of magnetic flux from the ship in place of the detector coils discussed previously. Since the loop extends over a large area the total flux linkages through it are no longer a direct measure of the field strength at any particular point and hence interpretation is not as simple.

Fixed Magnetometer Proving Grounds

Magnetometer proving grounds differ basically from the coil and loop ranges discussed previously, in that a reading of the total field (ship's field plus background) is made with the ship fixed in place. The ship's field is then obtained by subtracting the background reading.

The magnetometer used, which was developed by the General Electric Company, works on the principle that if the inductance in an a-c circuit varies differently over alternate halves of a current cycle, second harmonics are introduced in the current. The fundamental circuit consists of an exciter coil with a high permeability (Permalloy or Mumetal) core, a resistor, a d-c microammeter, and a source of a-c voltage all connected in series. The a-c voltage is such that the current flowing drives the core into saturation on both halves of the cycle.

If no external field acts on the core the inductance of the exciter coil is essentially zero for equal periods of time on both positive and negative halves of the cycle.

If an external field acts on the core of polarity so as to add to the coil field for positive current, the core remains in saturation, and the inductance is zero, for a longer period on the positive half of the cycle. As a result even harmonics are introduced in the current and its wave form shows a higher positive peak than negative peak. However, if the resistance is linear, it can be shown that no average or d-c component of current flows.

A d-c component of current is then obtained by using a nonlinear resistor with resistance which falls as the current increases. This direct current is a measure of the external field applied and is read on the microammeter.

In order to eliminate most of the alternating current through the microammeter a double circuit with a common leg containing the microammeter is used.

In the General Electric magnetometer, the detector unit contains two Permalloy cores with exciter coils wound upon them, a neutralizing solenoid enclosing the core and coil assembly, and two nonlinear resistors. The remaining components are contained in the control panel. The circuit just described is generally used only to indicate zero field; that is, act as a null indicator. Direct current is passed through the neutralizing solenoid and adjusted to such value that the microammeter in the null circuit indicates zero net field at the Permalloy cores, that is, the field due to the solenoid is equal and opposite to the external field present. The external field value is then obtained by measurement of the neutralizing solenoid current by means of a milliammeter, potentiometer or decade set with scale calibrated in milligauss.

Control panels using the foregoing basic circuits have been made for operation of up to 150 magnetometer detectors in succession. In some installations automatic recording is done by means of a modified Leeds and Northrup Speedomax strip chart recorder in conjunction with an automatic stepping switch on the control panel. On one installation an automatic recorder, designed by Bell Telephone Laboratories, typed out the field readings on a sheet of paper in the same arrangement as that of the magnetometer detectors in the proving ground array.

Portable Magnetometers

Portable magnetometers operate on the same basic principles as the fixed magnetometers used in proving grounds and no additional comment will be made.

Compensation of Effects of Degaussing Coils on Shipboard Magnetic Compasses by Use of Compass-Compensating Coils

R. A. ROBINSON
NONMEMBER AIEE

DEGAUSSING coils produce magnetic fields which counteract the external magnetism of a ship and thus afford protection against magnetic mines. These degaussing-coil fields in the ship cause the magnetic compass to deviate. Since the deviation changes as the degaussing currents are varied, permanent magnets cannot be used to compensate these errors as is possible in correcting errors in the normal adjustment of the compass. Compensation for the effects of the degaussing coils is accomplished by compass compensating coils mounted on the compass binnacle. Compass compensating coils neutralize the portion of the degaussing coil magnetic fields near a ship's magnetic compass which cause the compass to behave erratically. This is accomplished by producing compensating-coil fields at the compass which will be continuously equal and opposite to the degaussing fields at that point and will compensate for the errors due to degaussing.

Theory of Compensation

The installation of degaussing coils on all sizable vessels came as a sudden blow to navigation by magnetic compass. The previous complications resulting from variation and deviation were nothing compared with the tremendous changing deviations present when degaussing coils were energized. An initial attempt to use magnets to compensate magnetic compasses for degaussing-coil fields proved unsuccessful. Since it was desirable not to have to forego the use of the magnetic compass when the degaussing coils were energized, some means of correcting the degaussing deviation had to be devised. The use of compass-compensating coils solved this problem. This solution involved setting up a magnetic field at the compass position continually equal and opposite to the degaussing field at that point, using three mutually perpendicular coils connected to the degaussing coil through control resistors.

Figure 1 illustrates in one plane how the compass would be in error by angle θ if the earth's field, E, had superimposed on it the degaussing-coil field, D, at the compass. In this case, the compass would line up with the resultant of these fields, R, instead of with the earth's field as desired. Figures 2 and 3 illustrate two applications employing the 3-component principle of compensation. The first of these methods, illustrated by Figure 2, uses "cardinal" component coils for the horizontal effects, located as shown. The second method, illustrated by Figure 3, uses "intercardinal" component coils, displaced 45 degrees from the arrangement of Figure 2. In both cases, the vertical effects are compensated by a horizontal coil not shown.

Figure 1. Action of degaussing coil field in changing directive force at magnetic compass

Vertical Effect

Almost all degaussing coils create some vertical magnetism at the compass. Vertical magnetism at the compass causes the compass to deviate when the ship heels, even though the compass may have no deviation when on an even keel. The reason for this is that on an even keel the vertical degaussing component adds to or subtracts from the vertical component of the earth's magnetic field, whereas with the ship heeled, the vertical degaussing component inclines with the ship, thus producing a horizontal component, causing deviation on the compass. To compensate for this vertical magnetism caused by the degaussing coils, a compass compensating coil, called the heeling coil, is used. The heeling coil is placed in a horizontal plane around the binnacle, usually at the level of the compass needles, with its vertical axis passing through the center of the compass. A heeling coil is used as a part of all types of compass-compensating coils.

Horizontal Effect

In addition to providing compensation for the vertical component of the degaussing field, compensation must be provided for the horizontal component. Horizontal degaussing fields at the compass cause compass deviations whether or not the ship is on an even keel. This deviation due to degaussing on any heading may be obtained by subtracting the magnetic compass reading with degaussing coils de-energized from the magnetic compass reading with degaussing coils switched on. Compensation for the

Paper 48-228, recommended by the AIEE marine transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 22, 1948; made available for printing September 3, 1948.

R. A. ROBINSON is with the electrical branch of the Bureau of Ships, United States Navy Department, Washington, D. C.

Figure 2. Compensation with cardinal components

Figure 3. Compensation with intercardinal components

horizontal degaussing component is accomplished using two vertical coils, or pairs of coils, mutually placed at right angles. The magnitude and direction of compensation is changed as desired by varying the currents in each circuit.

Assuming that, in Figure 1, the arrows represent the direction and magnitude of the horizontal magnetic components of the earth's field, E, and one degaussing-coil field, D, at the compass when the ship is on a particular heading, it is necessary that the compass coils produce the component, D, which will cancel the effect of D.

Since E remains fixed with respect to the earth and D changes in direction with the ship's heading, the compass would be in error by an amount equal to the changing angle, θ, if the degaussing field, represented by the vector, D, were not counteracted by a compensating-coil field, represented by the vector, $-D$. The field, $-D$, can be produced by any two horizontal component magnetic fields at right angles, if the magnitude and polarity of each is adjustable. In compass compensation, these fields are produced by coils so placed that their effects are either fore-and-aft and athwartship (cardinal points of the compass) or displaced 45 degrees from the fore-and-aft and athwartship axes of the ship (that is in line with the intercardinal points of the compass).

It can be seen that the component, $-D$, is produced by either the cardinal set of right-angle coils shown in Figure 2 or the intercardinal coils in Figure 3. Similarly, any other desired horizontal field may be produced by a set of right-angle coils by merely adjusting the magnitude and polarity of the currents in the individual coils to produce components with the desired strength and direction. Since, in normal compass adjustment, the fore-and-aft magnetic effect is called B, this component in degaussing compensation is also called B; similarly, the athwartship component effect is called C. The intercardinal components (northwest-southeast and northeast-southwest) and the coils that produce them, are so termed because of the relative location of the coils on the binnacle, and also because these are the headings on which the coils are individually compensated. Thus, the magnetic component of an intercardinal coil which is in the forward-port/aft-starboard direction is called the northwest-southeast component and the coil which produces it is called the northwest-southeast coil. Similarly, the magnetic component produced in the forward-starboard/aft-port direction is called the northeast-southwest component and the coil which produces it is called the northeast-southwest coil.

Types of Compass Coils

In connection with the actual construction details of the various compass coils, it is sufficient to illustrate each coil type, point out the reasons for that particular design and mention the limitations in each case, and then proceed to a discussion of some of the engineering problems encountered.

The type A compass coil set, consisting of multiconductor cable wrapped about the binnacle as necessary to furnish the required compensation, provided temporary compensation for dozens of different binnacle sizes on hundreds of merchant vessels until new construction binnacles were standardized on naval and merchant vessels. Figure 4 illustrates a type A heeling coil on a merchant vessel binnacle.

The "Mark I" coil, which is another unusual arrangement tried experimentally at first, involved the use of a large vertical coil moved physically about the binnacle to line up the coil with the degaussing field at the compass. The cumbersome size and method of physical alignment with magnetic effect, led to an early abandonment of this design.

The first standardized coil assembly was the type B unit, illustrated in Figure 5. It will be noted that this design employed the soft-iron correctors of the compass as cores for the B and C compass-compensating coils. When the size or location of the Flinders bar or quadrantal spheres was changed, the compass had to be recompensated and the ship reswung for new deviation curves.

PLATE B

PLATE C

Figure 8. Type T compass coil mounted below magnesyn compass transmitter

Plate A—Front view
Plate B—Coil mounted with magnesyn transmitter and special mounting bracket
Plate C—Type T coil disassembled

To make degaussing compensation less affected by change in position and size of the normal soft-iron compass correctors, a system of coils mounted intercardinally rather than cardinally, was devised. These coils, designated type *G*, are illustrated in Figure 6. The only troubles encountered with this design were a fringe effect and lack of mechanical rigidity, both of these troubles causing no concern under all normal conditions. When degaussing fields, equal in strength to three or four times the earth's horizontal field, are compensated, this fringe effect becomes important, particularly if the *G* coils are close to the compass. This fringe effect is caused by a greater concentration of field around the edges of the coil rather than near the center and is eliminated on later designs by either lowering the intercardinal coils (if they are used in pairs) or using the return rather than the direct field.

An unfavorable condition common to both type *B* and type *G* coils is the possibility for misalignment. This is solved on subsequent designs by assembling all coils into one unit so that the three sets of compensating components remain permanently at right angles.

The type *K* arrangement employs rectangular intercardinal coils hung beneath the heeling coils as illustrated in Figure 7 to produce a direct field for horizontal compensation. The whole assembly is enclosed in a drawn metal case which fits over-all standard-shaped binnacles. This arrangement is standard for all large-size direct-reading compasses. The heeling coil appears in Figure 7 just below the top of the binnacle and the intercardinal coils in the downward extensions adjacent to each sphere.

The type *T* coil assembly, illustrated in Figure 8, employs three sets of windings which are concentric, mutually perpendicular, and wound on a common cylindrical core. This triad coil unit is in a cast aluminum enclosure which is mounted beneath the compass to be compensated. Primarily, it is intended for mounting directly beneath remote-reading magnetic-compass transmitters.

The type *R* coil assembly, illustrated in Figure 9, is mounted inside the binnacle, close to the magnetic compass. The type *R* and type *T* arrangements differ in principle from the type *K* arrangement in that the return field, rather than the direct field, is employed for horizontal compensation.

The shallow, wide R-coil, shaped like a doughnut, is tailor-made to fit inside the binnacle of a new design compass and around the compass corrector magnet assembly, thus taking virtually no additional space.

Current Control for Compensating Coils

In order for the compensating coil field to be always proportional to the degaussing coil current, the compass-compensating circuit supply voltage is tapped off the degaussing-coil series resistor or across a number of turns of the degaussing coil. This voltage is impressed upon the type *A* control-box resistors as shown in the left-hand diagram of Figure 10. The compass coil windings are tapped off the resistance windings.

Figure 9. Disassembled view of type *R* coil showing coil arrangement (left) and cover (right)

Figure 10. Type *A* control box wiring diagram

Control Box

The type *A* control box is used to set the compass coil currents. It consists of a watertight enclosure having a removable cover and contains three sets of control resistors for compensation. Each set is connected to one terminal strip, as shown in Figure 10, on which the resistance values are marked.

Each set of control resistors permits reduction of voltage from that of the supply leads from the degaussing coil to the voltage required for a particular compass coil winding and consists of three fixed resistors in series with a variable resistor. The entire control circuit is connected across the supply leads from the degaussing coil. Part or all of the series resistors are short-circuited as necessary, using jumpers supplied with the control box, to obtain the minimum voltage across the variable resistor that will permit fine control of the current to the compass coil winding. Since the degaussing field is seldom in line with any of the three compass coil axes (particularly when intercardinally mounted coils are employed) the three control circuits are connected in parallel across the supply leads from the degaussing coil, one circuit being used for each of the three magnetic components. As a result, one control box is normally required for each degaussing coil affecting the compass.

Engineering Problems

Use of a ferrous core to reduce space requirements presents a few interesting problems not encountered in ordinary coil design. If the coil with ferrous core is mounted close to the compass, interaction between the compass needles and the ferrous core occurs. The induction in the core from the compass needles results in quadrantal compass deviations (four alternate positive and negative half cycles, changing in accordance with the sine or cosine of twice the angle of heading). Increasing separation between core and compass magnets, in order to decrease interaction, results also in an increased size of the compass coil so that very little, if any, net reduction in size and weight results from the use of ferrous cores. If used, the core material must have very low hysteresis when magnetized sufficiently to produce fields at the compass between $\pm 1/2$ gauss (the scarcely measurable nonlinearity of one milligauss, when present for example as a hysteresis effect, results in the very appreciable error at the compass of 1/4 degree).

The problem of waterproofing coils for use in all weather deserves special attention. If the coil is small, like a type *T* coil, cast-aluminum housings with covers screwed tight against gaskets prove very effective, but on larger designs requiring drawn metal enclosures, the problem of obtaining satisfactory soldered joints is serious. Even with tin-plated joints, exacting fits, meticulous soldering, and subsequent pressure tests, the joints cannot be depended upon with absolute certainty. Apparently, the only way to insure watertight integrity of such coils is by the use of a suitable filling compound, applied after assembly and wiring are completed. Although this adds dead weight to the assembly, all units which have been properly filled performed excellently without failure.

While degaussing coils produce fields at the magnetic compass of magnitudes that would make readings entirely unreliable, compensation by compass coils used in conjunction with the degaussing installations reduces resultant deviations to within a few degrees. Allowance for the small remaining uncompensated portion of the deviation may be made by the navigator by means of a deviation card (a tabulation of the deviations on various headings). The use of several different prefabricated types of compass coils allows for simple installation on nearly all binnacles.

No Discussion

Use of Propulsion Generators on Naval Vessels to Supply Shore Power

F. E. ANDERSON
NONMEMBER

W. H. FIFER
FELLOW AIEE

THE USE of propulsion generators on naval vessels for supplying emergency shore power has interested electrical engineers for many years. During World War II the Navy modified several electrically propelled ships to make them suitable for quickly supplying shore power to areas where the retreating enemy had destroyed or sabotaged existing shore plants. However, the modified vessels are not available or practicable for supplying shore power for indefinite periods to relieve existing shore generator capacity.

Historical Background

Ever since the turbine electric propelled aircraft carrier, *USS Lexington*, was used in 1929 to supply emergency shore power to the city of Tacoma, considerable interest has been shown by public utilities in the obtaining of emergency power from propulsion generators on naval vessels. The *USS Lexington* was used for one month to supply a load of 20,000 kw to make up a power deficit caused by temporary lack of water power. A step-up transformer was used to connect the 5,000-volt output of one propulsion generator to the 12,500-volt line of the power company. The transformer and necessary switchgear were mounted on a pier to which the vessel was moored and necessary additional control equipment was installed temporarily in the vessel's engine room.

Early during World War II, the use of naval vessels' propulsion generators for emergency shore power assumed high importance due to the need for ready availability of power generating facilities to replace or supplement that destroyed or damaged by the enemy when retreating. Also, during World War II, there were constructed a large number of a-c turbine electric propelled vessels which had possibilities for supplying shore power.

One of the most notable instances of wartime requirements for emergency shore power was at the French port of Cherbourg in the summer of 1944. This port was one of the Allied targets in the initial assault on the European mainland since its port facilities were vitally needed for moving in Allied supplies. In retreating, the Germans had severed the 33,000-volt transmission line from the central power plant at Caen from which nearly all the power for Cherbourg had come. The only generating capacity remaining available to the Allies was an old standby steam power plant with two turbine generators, each rated at 900 kva. The Germans had left these units intact upon the plea of the French plant manager.

However, the Cherbourg steam plant was inadequate to supply all the power needs and, while operating with only one generator on the line, the unit was overloaded and burned out. The confused engineer on watch transferred the load to the second unit and burned it out, thereby leaving the entire area without any power, except for a few low-rated emergency generator sets. The situation was desperate and the success of the whole military operation hung in the balance.

In seeking generating capacity for Cherbourg, it was remembered that the *USS Donnell*, a United States Navy destroyer escort vessel with turbine electric a-c propulsion, was tied up in a British channel port awaiting disposition since 60 feet of the vessel had been blown off the stern by an enemy torpedo. An examination of the vessel showed that the propulsion equipment was in good condition and the vessel was towed to Cherbourg for possible use as an emergency power supply.

However, a transformer suitable for matching the 1,500-volt output of the propulsion generator at 50 cycles with the shore power line of 5,000 volts was required. A new transformer which the Germans had apparently overlooked was found in the French Naval Arsenal at Cherbourg. The transformer had a 6-to-1 ratio but upon opening it was found to have a center tap which would make it possible to reconnect for a 3-to-1 ratio, which was suitable to tie the propulsion generator to the shore system. The transformer was set on the pier alongside the vessel and within a short time power was being supplied. The vessel was able to supply about twice the rated power of the old standby steam plant and supplied power for a period of about six months until the normal power supply was restored.

Several months prior to the Cherbourg power emergency, the Bureau of Ships had started a study to determine the most suitable class of ships and the best type of equipment to supply emergency power whenever needed. The Cherbourg incident demonstrated very conclusively the need for vessels suitable for supplying emergency power to move in with invasion forces. The study showed that the turbine electric a-c propelled escort vessels were the best suited for this purpose and by September 1944 a contract was awarded to provide sufficient equipment to convert 15 of the escort vessels into emergency power vessels. The conversion equipment included a variable ratio transformer, switchgear, control and protective equipment, and high-voltage power cable which would allow a vessel to supply shore power at almost any point in the world. This equipment was designed especially with the thought that emer-

Figure 1. Close-up view on starboard side of destroyer escort vessel showing ship-to-shore cable reels and unit substation

gency shore power would be in great demand upon invasion of Japanese-held industrial areas and in the Japanese homeland itself.

The first vessel on which this special equipment was installed was the *USS Wiseman*. The installation was made in December 1944 by the Charleston naval shipyard at Charleston, S. C. and the unit was tested by tieing into the South Carolina Power Company system. This installation is illustrated by Figures 1 and 2. This unit proved to be entirely successful in these tests, and this initial installation was soon followed by similar installations by the Pearl Harbor naval shipyard on the *USS Whitehurst* and the *USS Marsh*, both a-c turbine electric propelled destroyer escort vessels, and sister ships of the *Wiseman*.

The value of the installation of this shore power conversion equipment was immediately demonstrated very conclusively. In April 1945, the United States forces moved into Manila, but the Japanese in retreating burned and sabotaged the city quite thoroughly with the result that a total of only 2422.5 kva of generating capacity was available in the city and this was in 14 emergency generator sets all over the city. Initially, the 14 sets were operated in parallel; however, in order to provide a more dependable power source, the *USS Wiseman* was sent to Manila and tied into the shore power system at 13,200 volts. The *Wiseman's* propulsion generators took over the entire load of the city and supplied a maximum load of 3,000 kw until the normal supply could be placed back in service.

Subsequent military successes in the Pacific, terminating in the end of hostilities in August 1945, obviated the need for additional shore power vessels and, as a result, no further installations of this equipment were made on the escort vessels.

In November 1945, the *USS Whitehurst* and *USS Marsh* were assigned to Guam to supply power for dredging operations in Apra Harbor. These vessels were operated in parallel with the power plants on shore, but operating difficulties were experienced due to voltage regulation in supplying power to the dredge. Special regulators were furnished for this service to provide for satisfactory operation of these vessels with the dredge. In order that the *Marsh* could be released for operation with the fleet, the Bureau of Yards and Docks outfitted the *USS Saranac*, an a-c turbine electric propelled tanker to supply power for dredging operations at Guam until the permanent shore power facilities could be completed. The *Marsh* was subsequently sent to Kwajalein during May 1946, to supply shore power at that location when the shore generating facilities failed during the preparations for the "Crossroad" atomic bomb tests at Bikini Atoll.

It became apparent soon after the end of the war that generating capacity in the United States was being taxed with an ever-increasing load, and the Navy considered that the shore power units should be kept in readiness for possible emergency use. Since the installation of the substation equipment in a destroyer escort vessel resulted in a reduction in its military effectiveness and added a considerable amount of topside weight which was not desirable, it was decided to retain the remaining substations on shore and, when needed for emergency use, to set the unit up on a pier or barge, with the vessel moored alongside much in the same manner as the *USS Lexington* and *USS Donnell* had been used. In order that a number of these vessels might be in readiness for such duty, the installation of control and power cables on a number of vessels of the turbine electric escort type was authorized. With the installation of these cables, the vessel could be readily connected to the unit substation mounted alongside and supply shore power.

The first experience in the use of this type of installation was obtained in New York City in May 1946. Power production for New York City was imperiled by a coal strike. Since lack of coal would shut down nearly all railroad and harbor tug traffic, the bulk of the city's food sup-

plies would have to come in by way of motor truck through the Holland and Lincoln vehicular tunnels, and it was imperative that power be available for ventilating these tunnels. In anticipation of the requirement for this emergency power, the destroyer escort vessels *USS Foss* and *USS Maloy* were ordered to have the shore power wiring installed and to be put in readiness to supply power to the tunnels. The installation was completed with the unit stations and high-voltage cable installed on barges for use alongside the vessels. Fortunately, the coal strike ended in time and the vessels were not required to actually supply power for this purpose, but the equipment was tested at the New York Naval Shipyard and operated satisfactorily, demonstrating the practicability of the use of such an arrangement.

The Navy has a large number of various types of vessels which have been placed in an inactive status and berthed in groups at various locations along the coasts. In Green Cove Springs, Florida, such a berthing area is provided for a number of vessels, but no shore power is available to operate dehumidifying machines, lights, and other essential electric services for these vessels. A high line is now being erected from Jacksonville to Green Cove Springs, but during the interim period, two destroyer escort vessels, the *USS Harmon* and the *USS Whitehurst*, have been supplying shore power.

During the fall of 1947, a serious drought in the New England states, especially Maine, drastically reduced the hydroelectric power output and resulted in an emergency situation insofar as the use of electric power was concerned. In November 1947, the *USS Maloy* and the *USS Foss* were assigned to temporary duty at Portland, Maine, in order to supply emergency power for the processing of foodstuffs, especially potatoes. The vessels were docked at a pier in a South Portland shipyard and the unit substations placed on the pier alongside the vessel. This installation is illustrated by Figures 3, 4, and 5. Due to the high tides at South Portland, it was necessary to provide cable gantries and sufficient slack in the cables to accommodate the rise and fall of the tide, as shown in the illustrations. The secondary of the substations supplied power to the Central Maine Power Company at 11,500 volts. The power output from the two vessels was about 9,000 kw and was cascaded up to Aroostock County in Northern Maine through the lines of the Central Maine, Bangor Hydro, and Maine Public Service power companies. These vessels supplied this load satisfactorily for a period of about five months.

Technical Considerations

In adapting the vessel's propulsion generators to shore power service, there are several differences between the use of the generators for propulsion service and for shore power supply purposes which must be considered. These include the following:

1. The generators supply only one or two loads for propulsion service as compared with a large number of loads in shore service. All of the Navy a-c turbine electric drive vessels with the exception of the old electric propelled battleships and aircraft carriers have either one or two propellers each driven by a propulsion motor with an associated propulsion generator. If the vessel has only one propeller, only one propulsion generator and motor are provided, and the only load supplied from the propulsion generator will be the propulsion motor, except in the case of certain tankers on which power is supplied also to the cargo pumps for taking on and discharging cargo. If the vessel has two propellers, as is the case of the destroyer escort vessels, two propulsion motors and generators are provided, and each generator can supply power to one or both motors depending upon the vessel speed desired. With one generator supply-

Figure 6. Ship-to-shore power control cubicle located in forward engine room of a destroyer escort vessel

ing both motors, the other generator is not supplying power. The generators are not operated in parallel.

2. Variable frequency is used for propulsion service as compared with constant frequency for shore service. Since synchronous propulsion motors are used to drive the propellers, the motor speed is varied by varying the generator frequency. This requires regulation of the generator voltage on a constant volts per cycle basis rather than for constant voltage as required for shore service.

3. No circuit breakers are used in propulsion service. Since the propulsion generator and propulsion motor form a complete power system, the power to the motor can be cut off by de-energizing the complete power system which is done by removing the field excitation from the generator rather than by disconnecting the motor by the use of circuit breakers.

4. Propulsion generators are not operated in parallel. As pointed out in paragraph 1 each generator forms a separate power system and does not require operation in parallel with another generator. This eliminates the need for paralleling equipment which is required normally in the operation of a power plant.

In order to utilize the propulsion generators on the a-c turbine electric destroyer escort vessels, shore power conversion equipment, referred to previously, was provided. This equipment provided control panels for each of the vessel's two engine rooms, and a power transformer with switchgear equipment for installation on the vessel or on a pier or barge alongside.

The control panels each contain synchronizing equipment, including phase rotation lamps and a synchroscope, to enable the propulsion generators to be paralleled with each other and with the shore supply when tieing into an energized system. Provided also on this panel are meters for reading the generator kilowatts and volts. The control panel is installed adjacent to the vessel's propulsion control panel as illustrated in Figures 6 and 7.

The power transformer is a 3-phase forced-oil-cooled transformer with variable voltage secondary. The primary is connected in delta for 1,725 line volts at 60 cycles, or 1,450 line volts at 50 cycles. A voltage adjusting handwheel is provided so that the primary voltage can be reduced in about $2^1/_2$ per cent increments to 1,552 volts at 60 cycles and in about 3 per cent increments to 1,277 volts at 50 cycles. The secondary is provided with adjustable links which will provide 7,200 and 21,600 volts in a delta connection and 12,500 and 37,500 volts in a Y-connection. A tertiary winding is included also which will permit operation at 2,400 volts delta and 4,160 volts Y, but the power output at these voltages is only 1,667 kva as compared with 4,500 kva at the higher voltages and 60 cycles. The power output at 50 cycles at the higher voltages is 3,750 kva. Provision is made also in the tertiary winding for bringing out the neutral of the Y-connection to provide a 4-wire system. The secondary voltages were chosen after a study of the usual transmission line voltages thoughout the world in order that the unit might be tied in with a power system at most any point in the world, with especial consideration given to the Far East.

The switchgear consists of two General Electric magne-blast AM 5-100, triple-pole circuit breakers, single-throw type, rated 5,000 volts, 1,200 amperes with 100,000 ampere interrupting capacity. The circuit breakers are located on the generator side of the transformer, and each circuit breaker enables its associated generator to be removed from the line. The circuit breakers are of the metal-clad draw-out type and have remote closing from the engine room control panels. The propulsion equipment has phase balance and ground protection when operated to provide ship propulsion. These phase balance and ground protective relays, when operated during propulsion service, trip open the field circuits of the generator, de-energizing the propulsion system. For shore power service, additional protection is provided in the form of overload and reverse power protection, and the four protective relays phase balance, ground, overload, and reverse power, are placed in the circuit breaker trip coil circuit to trip out the circuit breakers in the circuit in which the fault occurs.

The switchgear and transformer with the required auxiliaries are assembled together to form a unit substation of the outdoor-type as illustrated in Figure 8. The total weight of this unit with oil was designed to a limit of 45,000 pounds in order that it might be handled by crane facilities available aboard Navy tender ships.

The power rating of the substation is based upon the rating of the generator operating at 3,600 and 3,000 rpm. The generator stator and rotor heating determines the maximum output of the generators. For propulsion service, the generators are rated at 4,600 kva, 5,600 rpm, and 93.3 cycles, but, slowing the unit down to 60 and 50 cycles, the ventilation is reduced since these units are self-ventilated. This reduced ventilation requires a reduction in the field and stator amperes in order to prevent overheating.

In order to provide for running the high-voltage lines from the transformer secondary to the shore in those cases where the lines must be carried over water, special high-voltage submersible cables were designed. One type cable is rated at 13,500 volts and the other type rated at 37,500 volts. Cellular rubber floats are provided to be attached to the cable to provide the necessary buoyancy to float the cable from the barge or vessel to the shore as illustrated by Figures 9 and 10. Special motor-driven reels are provided for this cable along with a foundation structure which will accommodate two 1,000-foot reels of cable. One reel of 13.5 kw cable and one reel of 37.5 kv cable have been provided for each unit substation equipment. The two cable reels and supporting structure as mounted on a vessel are illustrated in Figure 1.

For propulsion service, voltage regulation is provided by means of an amplidyne regulator which maintains constant volts

Figure 7 (left). Ship-to-shore power control cubicle located in after engine room of a destroyer escort vessel, showing the vessel's propulsion control cubicle on the left

Figure 8. Front view of unit substation from cooler compartment end, showing high-voltage bushings, ratio adjusting handwheel, and water-tight doors to the circuit breakers on the left

Figure 9. Submersible high-voltage cable with floats attached

per cycle. This type of regulator will allow proper voltage regulation for a shore power system which requires constant voltage regulation provided the frequency is held constant. However, this regulator will not provide for proper reactive kilovolt-ampere load division between two generators which are paralleled on a bus without any reactance between the two generator terminals.

In the design of the shore power unit, it was considered that manual regulation would be satisfactory since the units would supply loads which did not have large instantaneous load variations and this has proved to be the case with the exception of the shore power operation at Guam. In this instance, the load was a dredge with a 1,000-hp induction motor-driven cutter and a 3,000-hp pump. When using only one destroyer escort vessel to supply power, starting of the 1,000-hp cutter motor caused the voltage at the dredge to drop about 50 per cent which opened the dredge circuit breaker and made it impossible to start the dredge machinery. Operation was satisfactory when the vessel was paralleled with the shore supply of 1,400 kw which had voltage regulators, but this type of operation proved to be too difficult since it was necessary to provide manual division of load and reactive kilovolt-amperes and maintenance of system voltage at three power generating stations by telephone communication under conditions of fluctuating load. In order to provide proper voltage regulation and division of reactive kilovolt-amperes for the vessel's two generators when operating in parallel, the regulators used for propulsion service were modified on each of the three destroyer escort vessels on which the permanent installation of the substation equipment had been made. This modification consisted of providing for division of the reactive kilovolt-amperes by means of cross-current compensation between the two generators and providing compensation for transformer reactance voltage drop and cable resistance voltage drop in order to obtain better voltage regulation at the load.

The unit substation, including the transformer and switchgear, and the engine room control panels, were supplied by the General Electric Company. The high-voltage cable was supplied by the Okonite Company, and the cable reels and supporting structure were provided by the Norfolk Naval Shipyard. The cable floats used for the high-voltage cable were furnished by the Sponge Rubber Products Company.

Operational

In the operation of these units, there are several factors which must be considered in order to insure satisfactory operation of the propulsion plant. The vessel must be located in a sufficient depth of water so that the condenser intakes will not become clogged with silt. In order to minimize the possibility of silt clogging the condensers, the vessel should have a depth of at least five feet of water below the keel at low tide. When operating in shallow water, the condenser tubes should be blown every six hours. Since the maximum power which can be delivered from the substation is only one-half the full power rating of the propulsion machinery, the full power can be supplied from one boiler, if necessary, for a short period while routine maintenance work is carried out on the other boiler and thus maintain continuity of power supply.

In preparing an operational schedule for the operation at Portland, Maine, referred to previously, it was considered that the vessels would supply power for six days a week, Monday through Saturday, and routine maintenance would be carried out on Sunday. However, the performance of these plants was so creditable that it was not necessary to shut down every Sunday for maintenance. The operating score for the four plants on these vessels showed an operating time of a total of 10,741 turbine hours with only 791 hours off the line, or an availability of 92.5 per cent. The majority of these 791 hours out of service were for normal planned maintenance at times when the power system loads were low. A total of 24,220,000 kilowatt-hours, or an average of 4,500 kw per vessel, were supplied during this period. The vessels are able to supply their own ship's power requirements from the ship's service power plant, making it unnecessary to provide any shore power services to the vessels.

The cost of power production by naval vessels is high due to the fact that the vessel must be fully manned, thus entailing a large operating crew. The total cost of power from a vessel in active service,

Figure 10. Submersible high-voltage cable with floats attached running to power station ashore

including both the direct charges of power production and the fixed charges, would be several times the cost of power from a shore power plant. If the vessel were taken from the Reserve Fleet, the total cost of power would be further increased since the reactivation and represervation cost must be included also.

Conclusions

Operating experience has shown that it is practicable to use propulsion generators on naval vessels to supply emergency shore power. However, it should be pointed out that the propulsion generators and associated equipment on naval vessels are not designed as a source of shore power supply. The primary mission of a naval vessel is as a fighting vessel and all equipment is designed to perform most efficiently in this function. For that reason the frequencies and voltages of the generators are quite likely not to be those commonly used for power on shore, as in the case of the destroyer escort vessels. This results in not being able to utilize fully, when supplying shore power, the generating capacity of the plant and requires that considerable auxiliary equipment be added to enable the vessel to supply shore power.

There appears to be a popular misconception that any large naval vessel is capable of supplying appreciable amounts of shore power. This assumption is probably due to the publicity given when the *USS Lexington* was used to supply 20,000 kw of shore power to Tacoma, Washington, in 1929. The *Lexington* and her sister ship, the *USS Saratoga*, both of which have been lost at sea, were the only modern United States aircraft carriers which have ever been equipped with electric propulsion. The only battleships which are fitted with electric propulsion are the *Maryland*, *California*, *West Virginia*,

Colorado, and *Tennessee*. However, the electric propulsion plants on these vessels are designed for operation at approximately 35 cycles and are therefore not suitable for supplying 50 or 60 cycle shore power. No other aircraft carrier, battleship, or cruiser is fitted with electric equipment suitable for supplying shore power.

With the exception of the vessels in active service for training, naval maneuvers, and special assignments, the majority of the destroyer escort vessels employing electric propulsion have been inactivated and placed in the reserve fleets. To use a destroyer escort vessel for shore power purposes would involve removing a vessel from its assigned duties with probable interruption to the entire fleet or force to which it is assigned or would require a vessel in the reserve fleet to be reactivated. To reactivate a vessel not only requires time and money, but requires a new crew to be assembled to operate it.

It has therefore been the past policy of the Navy Department to authorize destroyer escort vessels to supply shore power only when an emergency involving health or conditions affecting the nation as a whole are involved. The contemplated supply of power to ventilate the Holland and Lincoln tunnels in New York and the supplying of shore power to the state of Maine to process food stuffs are examples of where use as shore power supplies have been approved. It should be especially noted that the vessels are used only to carry over some acute emergency and have not been authorized for indefinite use merely due to shortage of generating capacity. The relatively small output combined with the need of the vessels in the fleet, the lack of crews and cost of reactivating the vessels, makes them entirely impractical for shore use except in extreme emergency conditions.

Discussion

L. W. Bates (Captain U. S. N. R., Ret., Navy Department, Washington, D. C.): The use of propulsion generators on Navy ships to supply shore power is subject to limitations since the voltages and frequencies at which they normally operate are not suitable for use on shore. This requires the installation of special equipment and also reduces the amount of power available for shore use considerably below the rated capacity of the generators.

The armed forces however, have, or had, a number of mobile generating plants which were designed especially for furnishing shore power in emergencies at standard voltages and frequencies. The majority are 60-cycle plants but a few were arranged for operation at either 50 or 60 cycles.

The largest plants of this character were four special barges, each having a capacity of 30,000 kw, designed and built with funds supplied by the Defense Plant Corporation and operated by the Department of the Army. Primarily intended for use on the inland waterways of this country, they had a draft of only nine feet. Later developments however, required their use abroad so that certain structural changes were made to three of the plants including the installation of bows on the barges, to facilitate towing across the ocean.

These plants use either oil or gas as fuel and the generator voltage is 13,800 with a transformer for stepping up the full output to higher voltages suitable for interconnection with existing high-voltage transmission systems on shore.

It is of passing interest to note that these plants were given the following names: *Seapower*, *Inductance*, *Impedance*, and *Resistance*.

Three of the plants were declared surplus after the cessation of hostilities and were sold by the War Assets Administration and the remaining one is still owned by the Government and is in use in the Far East.

The Department of the Navy has one floating power plant, the *Jacona*, of 20,000 kw capacity which is now about 15 years old. It was built originally for one of the New England power companies, was commandeered during the war and later towed to Pearl Harbor to supplement the generating capacity of the public utility company in meeting its war-time demands pending completion of the installation of a 40,000-kw generating unit in one of its plants. This vessel is now supplying emergency power in the Far East.

The Navy also has two 10,000 kw railway mounted power plants, each comprising a train of six cars as follows: turbine car, boiler car, switchgear car, transformer car, and two cars for various auxiliaries, one of which is a gondola car and the other a box car. One plant is located on the west coast and the other in the east from where they can be transported at short notice to any naval establishment within the continental limits if a sudden emergency power demand should develop. These plants burn oil and voltages of 2,400, 4,160, 11,000 and 13,800 are available to permit interconnection with the electric system of any naval activity.

Fortunately there were no failures of the normal power supply for naval establishments during the war nor were there any instances of power damage due to sabotage or bombing so that these plants were not used directly for military purposes. They were however, used indirectly to contribute to the war effort when they were at times leased to a synthetic rubber plant and to several public utility companies whose normal power output was seriously curtailed due to drought conditions. During such periods as the plants were leased, it was of course understood that they would be returned immediately to naval custody at any time if needed to meet emergency naval needs.

A complete description of the railway mounted plants with illustrations was given in a paper before the American Society of Mechanical Engineers in December 1944.[1]

The armed forces also have a number of smaller mobile Diesel-driven generating plants mounted on railway cars and truck trailers which have been of material assistance in many cases.

It is expected that additional mobile power plants of various types and sizes will be obtained from time to time to be available for future emergencies and that consideration will be given to the possible use of gas turbine driven generators in some cases.

1. 10,000 Kv Railway-Mounted Mobile Steam Power Plants for the United States Navy Department, Bureau of Yards and Docks, **Edwin Lundgren, L. R. Biggs.** *Transactions*, American Society of Mechanical Engineers (New York, N. Y.), volume 67, pages 141–65.

F. M. Starr (General Electric Company, Schenectady, N. Y.): This paper is especially noteworthy in clarifying in concise terms the limited degree to which propulsion power can be made available for shore installations.

Even if electric propulsion power were abundant, it normally could not be justified for shore use under any except emergency conditions. All components of cost are high: power and energy losses are high; maintenance is high; and operating efficiencies are low.

In recent years, the power companies have shown considerable interest in mobile floating power plants designed for the purpose and not necessarily utilizing propulsion generators. They have many attractive features not only for emergency outages, but also to take care of seasonal peaks, water shortages, unanticipated load growth, and so forth. Such applications have gained little headway, however, primarily because of the high initial cost.

The authors have discussed in detail the satisfactory performance of the turbine-electric destroyer escorts equipped with General Electric shore-power conversion equipment to meet war-time power emergencies and subsequent peacetime emergency applications. Late in 1944, the General Electric Company accepted contracts to design and manufacture on a rush basis, the necessary conversion equipment to permit rapid transfer from propulsion to shore power on 15 destroyer escorts.

One of the major problems was to incorporate enough flexibility in the equipment to insure adequate parallel operating performance at both 50 and 60 cycles and at a number of operating voltages, the exact values of which could not be known in advance.

This was solved by arranging for six nominal output voltages with four primary full capacity taps on the transformer fully co-ordinated with the available range in field currents on the generators.

The preliminary tests on the first ship at the Charleston Naval Shipyard demonstrated that:

1. The two propulsion turbines and generators could be operated successfully in parallel.

2. Uniform kilowatt load division could be obtained provided the propulsion speed levers were equipped with vernier position adjusters.

3. The two ship's turbines could be paralleled successfully with a large power system even though the nominal voltage of the ship's output and the operating voltage of the power system were substantially different.

4. Balanced reactive kilovolt-amperes could be successfully maintained by manual field control.

5. The ship's generators could be operated at a leading power factor of 90 per cent (obtained with reduced fields) without any danger of instability.

6. Temperature rises expected at rated kilowatt and kilovolt-amperes outputs of the generators and transformer were not exceeded.

As noted by the authors, difficulties were encountered in dredging operations at Guam and an attempt was made to correct them by the installation of voltage regulators. However, subsequent analysis of this particular problem indicates that there was not sufficient kilowatt capacity to handle the power surges which are inherently characteristic of dredge pumps. One of the important limitations on the application of the propulsion power of a small vessel for shore use is the size of the larger motors which must be started. Vessels such as the destroyer escorts are best suited to small diversified loads.

Origin of the Electric Motor

JOSEPH C. MICHALOWICZ
MEMBER AIEE

THE DAY that man molded the first wheel from the sledlike skids of his primitive wagon should be one of great commemoration, had not its identity been lost in the passing of time. Not unlike the wheel and probably second only to the wheel, the electric motor has been a great benefactor to man and its history, too, slowly is being forgotten.

Today, we hear very little, if anything, about Thomas Davenport, the blacksmith who invented the electric motor; or about De Jacobi, who propelled the first boat by means of an electric motor; or of Charles Page who successfully carried passengers on the first practical electric railway. Had it not been for the efforts of these men and others like them, the benefits of the electric motor probably would not be enjoyed today. It is the purpose of this paper, in general, to trace briefly the early history of the science of electromotion and, in particular, to bring to light and to honor the inventor of the electric motor.

Early History

The development and rapid growth of our electrical science and the electrical industry can be followed very easily through the growth of the basic principles. The basic principle governing the operation of the electric motor is, of course, that of the production of motion by the use of magnetic fields. Legend tells us that the first exercise of this knowledge probably is accredited to Hoang-Ti, the mythical founder of the Chinese empire, who was the first to construct a magnetic compass in 2634 B. C. Factually, the citation delivered by Andre-Marie Ampere in 1820 A.D. of the nature of the electric current and its relation to magnetism was the classic truth that was necessary for the development of the practical motor. Not quite a year later, Michael Faraday, using this information, produced rotation of a wire carrying electric current, around a magnetic pole. But it was not either of these two illustrious men who deserve credit for the development of the practical electric motor. There were others, some talented, some not, some prophetic, some curious, who, through discouragements and failures, were directly responsible in giving us the modern electric motor. Briefly, these early achievements up to the year 1850, may be listed as follows:

1821—Michael Faraday demonstrated for the first time the possibility of motion by electromagnetic means with the movement of a magnetic needle in a field of force.

1829—Joseph Henry, a teacher of physics at the Albany Academy in New York, constructed an electromagnetic oscillating motor but considered it only a philosophical toy.

1833—Joseph Saxton, an American inventor, exhibited a magnetoelectric machine before the British Association for the Advancement of Science.

1837—Thomas Davenport, an American inventor, obtained the first patent on an electric motor.

1838—Solomon Stimpson, an American, built an electric motor having 12 poles and a segmental commutator.

1839—Moritz-Hermann De Jacobi, a Russian scientist, demonstrated the use of the electric motor to propel boats.

1840—Truman Cook, an American, built an electric motor having a permanent magnet armature.

1840—Robert Davidson, a Scot, built a lathe and a small locomotive powered by electric motors.

1845—M. Froment, a Frenchman, built an electric motor similar to a "breast wheel, whose paddles were acted upon by magnetism instead of water."

1847—Moses G. Farmer, an American, constructed and exhibited a 2-passenger car and locomotive driven by an electric motor.

1850—John Little, an American, constructed an electric motor having radially arranged permanent horseshoe magnets.

1850—Charles G. Page, an American, developed a solenoid-type electric motor.

Although these accomplishments and the many others that took place in the years following 1850, helped considerably in the design of our present electric motor, the most outstanding efforts were those of Davenport, De Jacobi, and Page. These are significant because Davenport's machine was, without a doubt, the first practical electric motor; De Jacobi's apparatus demonstrated the first practical application; and the device of Page showed the possibilities of a different motor design.

The Davenport Motor

Thomas Davenport, the rightful inventor of the electric motor, spent a life that seems more fictional than factual. His rigid understanding of the motor's principles, his clear vision of the possibilities of such a device and his driving persistence to establish a foundation for a discovery too early for its time, easily should qualify him as a member in the society of Ampere, Faraday, Morse, Bell, and other immortals of the electrical science. To understand the trials of this early American inventor, it would be unwise not to present at least a slight glimpse into his early life.

That Thomas Davenport came from true American stock, there can be no doubt. His ancestors came to Dorchester, Mass., prior to 1640, a short time after the landing of the Pilgrims. His grandfather was a soldier in the War of the American Revolution and he had two brothers in the War of 1812.

The inventor, one of 12 children, was born in Williamstown, Vt., on July 9, 1802, of poor, though patriotic and reli-

Paper 48-232, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted July 2, 1948; made available for printing July 30, 1948.

JOSEPH C. MICHALOWICZ is a professor in the department of electrical engineering, at the Catholic University of America, Washington, D. C.

gious parents. His early boyhood consisted mainly of working the soil and tending the farm, but he did not neglect to obtain the little education that was available in those days. He took advantage of every possible moment in the classroom, even engaging in reading during the recess periods.

At 14 years of age, he became a blacksmith's apprentice. In this trade he was "bound out" for seven long years, with no compensation other than a knowledge of smithing and a 6-week term a year at school. Here again, he occupied his leisure time in reading books that he obtained from "auction" libraries.

At the end of his apprenticeship, though penniless, he started his own blacksmith's shop in the town of Brandon, Vt. He continued his trade for ten years until the year 1833 when his curiosity was aroused by a report that "a galvanic battery" which would "lift a common blacksmith's anvil" was on exhibition at Crown Point, N. Y. He instantly made the trip to Crown Point but was unable to view the device. Later reports informed him that this newly found wonder contained a horseshoe shaped magnet. These accidental references of "anvil" and "horseshoe" had excited him so thoroughly, that he made plans for a second trip to Crown Point. Not having the funds with which to finance this second journey, he persuaded his brother Oliver, a tin peddler, to take him in his peddler's cart.

Arriving at Crown Point, Davenport succeeded in viewing the "galvanic battery" which would "suspend an anvil between heaven and earth." It was an electromagnet invented a few years previously by Professor Joseph Henry of Princeton University. It consisted of a suspended horseshoe magnet about a foot long, wound with silk-insulated copper wire connected to a galvanic cell. It had been purchased by the proprietor of the Penfield Iron Works to separate the iron from the waste in the local low-grade ore. Davenport marvelled at the ability of this 3-pound magnet to raise an anvil weighing 150 pounds, and, imagining that this power could be put to more useful work, asked its purchase price. The price was $75. Again brother Oliver was called upon. Reluctantly, Oliver traded his wares, his cart, and his horse for the necessary $75 plus a worthless nag, and the magnet was purchased.

Having brought the magnet home, Davenport discovered that he could make the magnet lose its power by disconnecting one of the wires to the battery and could restore it again by holding the severed ends together. This simple electrical fact immediately convinced him that the power bestowed upon the magnet was controllable. The starting and stopping of an electric current by the making and breaking of an electric circuit revealed a most important fact, the discovery of which, simple though it may seem today, well could be accredited to Davenport, for there is no record to show that anyone else, even Joseph Henry, had performed such an experiment.

Overwhelmed by curiosity, Davenport began to dismantle the magnet—but not without care; for he summoned his wife, Emily, to take exacting notes of its construction. From these notes, he constructed a larger magnet, using the silk from his wife's wedding dress as an insulator between the conductors. The home-made replica was a success. He built more and larger ones and predicted that "steamboats would be propelled by this power" and that "it would replace the murderous power of steam."

Davenport's next objective was to convert the linear motion of the electromagnet into rotational motion and thereby make the flow of energy continuous. After much experimentation, he finally obtained rotational motion early in 1834. He accomplished this by mounting a magnetized iron bar horizontally on a bearing and held the electromagnet in such a position that its repulsion set the iron bar in motion. Then, by breaking the circuit by hand at properly timed intervals, he found that the iron bar could be kept in continuous motion.

Later, he built a better and larger motor, about which Davenport writes in his own memoirs:

> In July 1834, I succeeded in moving a wheel about seven inches in diameter at the rate of about 30 revolutions a minute. It had four electromagnets, two of which were on the wheel, and two were stationary and placed near the periphery of the revolving wheel. The north poles of the revolving magnets attracted the south poles of the stationary ones with sufficient force to move the wheel upon which the magnets revolved, until the poles of both the stationary and revolving magnets became parallel with each other. At this point, the conducting wires from the battery changed their position by the motion of the shaft; the polarity of the stationary magnets was reversed, and, being now north poles, repelled the poles of the revolving magnets that they had before attracted, thus producing a constant revolution of the wheel.

How Davenport actually reversed the flow of current through the electromagnets, his memoirs fail to state, but it probably consisted of some sort of a cam mechanism that did not operate very satisfactorily. But the satisfactory operation of his creation was of lesser importance than his successful attempts to convince others of the possibilities of this newly found aid to man. He had more followers who believed that he was developing a perpetual motion machine rather than a form of magnetic power. As the power developed by this early motor was only about 1/50th of a horsepower, those who viewed it, called it "mosquito power" and could see no practical value for such a device. His strong desire to establish his electric motor resulted in a neglect of his trade, a loss of customers, and near financial ruin. He sought encouragement from his village pastor who rebuked him with the statement, "If this wonderful power was good for anything, it would have been in use long ago." But undaunted by these setbacks, he took his motor to Middlebury College, there to seek the advice of the possessors of higher learning.

Professors Turner and Fowler of the Middlebury faculty watched a demonstration of the motor, recognized its potentialities, and advised Davenport to apply for a patent immediately. Elated, Davenport returned home and set about developing a new mechanism for reversing the flow of current through the electromagnets. In April 1835 he constructed a reversing mechanism that consisted of insulated segments rubbed by elastic flattened wires connected to the rotating armature. It was the inception of the modern commutator and it greatly improved the operation of Davenport's early motor. So enthusiastic was the press with this improvement that the August 13, 1835, issue of the Troy *Daily Budget* praised the accomplishments of Davenport and predicted that his name "would follow that of Henry's to the ends of the earth."

With continued encouragement from Professor Turner of Middlebury College, Professor Amos Eaton of Rensselaer Institute, Professor Joseph Henry of Princeton University, Professor Silliman of Yale University, and Professor Alexander Bache of Pennsylvania University, Davenport finally prepared a patent model and papers and presented them to the Patent Office. But misfortune followed him to Washington too, for the Patent Office burned and his model together with the papers was destroyed. However, with the aid of Ransom Cook, a prosperous manufacturer, another model was built and the papers rewritten. A photograph of this model, now on display at the Smithsonian Institution in Washington, D. C., is shown in Figure 2. He filed his claim again on January 24, 1837, and only 30 days later, on February 25,

Figure 2. Patent Office model of the Davenport motor

1837, received United States Patent number 132, a reproduction of which is shown in Figure 3. Here, without question, is evidence that Thomas Davenport is the inventor of the electric motor, about which the New York *Herald*, on April 27, 1837, so pompously stated:

> A Revolution in Philosophy—Dawn of a New Civilization . . . most extraordinary discovery, probably the greatest of ancient and modern times—the greatest the world has ever seen, the greatest the world will ever see.

The electric motor was not the only "first" for Thomas Davenport, for he built a model of the first electric railway, and, on the first electrically-driven printing press, which he built in 1839, he printed his own publication—"The Electro-Magnet and Mechanics' Intelligencer," the first American periodical on electricity. But, like the electric motor, they offered him no reward, and, in 1851, Thomas Davenport died penniless, with a broken heart, the patent on his electric motor having expired a few months prior to his death.

The De Jacobi Motor

On December 1, 1834, a Russian scientist, Moritz-Hermann De Jacobi presented a paper before the Academy of Sciences in Paris in which he stated that he had obtained rotation by electromagnetic methods in May 1834. Since Davenport wrote in his memoirs that he first succeeded in producing motion electrically in July 1834, the question of actual priority in the point of time, is a close one. If the results obtained by De Jacobi in May 1834 were effected by the same apparatus that he described in his paper before the Academy in December 1834, then the priority must be conceded to him, but there is no proof available to show that such is the case. However there is no doubt that the discoveries made by the two men were wholly independent.

In the year 1839, the Emperor Nicholas of Russia granted a sum of $12,000 to De Jacobi to enable him to prove that his electric motor had practical application. De Jacobi had a boat constructed, 28 feet long and 7 feet wide, which was propelled by means of paddles connected to an electric motor of his design. Figure 4 shows a model of the motor used on this craft. It consisted of two sets of electromagnets, eight in each set, one set being stationary and the other fastened to a rotatable wheel. Current from a bank of batteries was delivered to the rotating "star" through a commutator which reversed the polarity of the magnets eight times each revolution. The commutator used by De Jacobi appeared to be of better design than that used by Davenport and is very similar to the ones used today.

The De Jacobi boat, the first practical application of an electric motor, carried about 14 passengers and was powered by 320 Daniell cells, which is equivalent to about 100 of our present-day 6-volt storage batteries. In its trip up the Neva River it never achieved a speed greater than three miles an hour and consequently offered very little competition to man-propelled craft. The weight of the many batteries made the accomplishment impractical and it shortly was declared a failure. The cause of the failure was obvious, but the value of the electric motor as a new form of marine power was not forgotten.

The Page Motor

Charles Grafton Page, a physician from Salem, Mass., performed many electromagnetic experiments during the middle of the 19th century, the accounts of which may be found in Silliman's *American Journal of Science and Art*, the outstanding science publication of that time. In 1841 he became one of the two principal examiners in the United States Patent Office, and from 1844 to 1849 held the chair of chemistry at Columbian College, now George Washington University. In 1846 he built a small reciprocating electromagnetic engine which operated in an entirely different manner from that of Davenport's and De Jacobi's machines and, though the principle was sound, it never gained much popularity. Its motion resembled very much that of a steam engine's piston and in appearance was quite similar. It consisted of a hollow electromagnetic coil and an iron bar which was free to move within the coil. Both the coil and the bar were held vertically so that the bar was in a position of rest outside the coil when the coil was de-energized. Once current was allowed to flow through the coil, the bar would be attracted upward. Then when the current in the coil was interrupted, the bar would fall downward. This vertical motion was transferred to a flywheel by means of a crankshaft. A commutating

device, fastened to the crankshaft, automatically interrupted the flow of current to the coil at the proper time. In 1850, Page improved upon this single-acting motor by adding another solenoid which would pull the rod in the other direction and thus not depend upon the force of gravity for assistance. This improved model, for which Page was issued U.S. Patent number 10,480 dated January 31, 1854, is shown in Figure 5.

Although Page's motor did not receive public acclamation, it is worthy to note, as in the case of De Jacobi, that he made an outstanding contribution in publicizing the feasibility of such a device. In 1851, the Congress voted $50,000 to allow Page to construct an electric locomotive. A very interesting account of this early experiment may be found in the first American textbook on electric motors entitled "The Electric Motor and Its Applications," by Thomas C. Martin and Joseph Wetzler. Portions of this account as found on page 20 of this book are given here:

> Professor Page made a trial trip with his electromagnetic locomotive on Tuesday April 20, 1851, starting from Washington, along the tracks of the Washington and Baltimore Railroad. His locomotive was of 16 horsepower, employing 100 cells of Grove nitric acid battery, each having platinum plates 11 inches square. The progress of the locomotive was at first so slow that a boy was enabled to keep pace with it for several hundred feet. But the pace soon increased and Bladensburg, a distance of about five miles and a quarter, was reached, it is said, in 39 minutes. When, within two miles of that place, the locomotive began to run at a rate of 19 miles an hour, or seven miles faster than the greatest speed theretofore attained. This velocity was continued for a mile, when one of the cells cracked entirely open, and, as a consequence, the propelling power was partially weakened. Two of the other cells subsequently met with a similar disaster. It was found that the least jolt, such as caused by the end of a rail a little above the level, threw the batteries out of working order, and the result was a halt. This defect could not be overcome and Professor Page reluctantly abandoned his experiments in this special direction.

Page knew of Davenport's accomplishments in the field of electromagnetism and much correspondence passed between the two in which the merits of their individual devices were discussed. There were two major points of disagreement between them which time has shown that Davenport held the sounder theory. Page consistently adhered to the theory that the best results would be attained by simply discontinuing the flow of current to the electromagnets, without reversing the polarity. Davenport strongly persisted that the reversal should be performed. On the other point of argument, Page claimed that the size of the electric motor was definitely limited, since his experiments showed that the smaller machines were more efficient. Davenport could not see any sound foundation for such a claim and stated that such an idea affected him with "peculiar disagreeableness."

Conclusions

The efforts of these early pioneers, although seemingly failures, laid the necessary foundation for the development of the modern electric motor. Their accomplishments proved disappointing not because the soundness of the electric motor as a means of converting energy was in doubt, but rather because the device was born too soon. Since most crafts and skills were performed satisfactorily by hand at that time, the need of such labor-saving devices for mass production was not in demand. Also, the expense of the batteries to drive these primitive motors made its use prohibitive. Around the year 1850, Robert Hunt, an English natural philosopher, analyzed the relative cost of power obtained from a steam engine and from an electric motor using a battery and found that the electric power was 25 times more expensive than steam power. It did not occur to these early experimentors that the reverse process of electromagnetism was possible—that of the d-c generator. It was not until 1860 that Antonio Pacinotti, an Italian scientist, showed conclusively that by reversing the operation of the electric motor, "motion would produce electricity." Even after that discovery, industry was slow to make use of this knowledge. It was not until 1886 that the electric motor found its place in the American home when the Curtis, Crocker, Wheeler Company began manufacturing battery-operated motors for sewing machines. It was not until 1887 that the City of New York decided to lay the first tracks for its now famous "elevated." It was not until 1897 that the first electric automobile made its appearance. It was not until 1910 that the first electrically-driven washing machine was introduced to the American housewife. And it was not until 1915 that the *U.S.S. Mexico*, the first electrically propelled battleship, was launched.

Nevertheless, much credit should be given to those men who had the vision to foresee the marvels of their bundles of copper and steel. First to Thomas Davenport, the inventor of the electric motor; second, to Moritz-Hermann De Jacobi, who was the first to apply the electric motor practically to marine propulsion; and finally, to Charles Grafton Page, who was probably the first to apply successfully the electric motor to rail locomotion. Without a doubt, the most outstanding of these men is the Brandon blacksmith. In spite of the paucity of both his educational and financial advantages, he achieved a goal which others, far more fortunate than he, never had gained. His education could not have exceeded any more than three years of study based on today's standards and he was not gifted by any grant of money for the continuation of his experimental studies. Both De Jacobi and Page were learned men, fully equipped to battle the problems of their newly found science—electromotion. Moreover, their struggles were cushioned heavily by large governmental grants. It required supreme effort for a man, completely lacking such aids, to follow through to the time of his death an ambition that sprang from mere curiosity and resulted in one of man's most useful devices. It is hardly necessary to point out what fortunes would have been his had he renewed his patent rights and had he lived a few decades longer. The claims of his patent were extremely broad:

> Applying magnetic and electromagnetic power as a moving principle for machinery in the manner above described, or in any other substantially the same in principle.

What with an estimated 50,000,000 motors manufactured in the United States during the year 1947, a possessor of such a claim easily could mass a fortune far exceeding that of Rockefeller and Carnegie combined. But neither fame nor fortune was the lot of Thomas Davenport, a man who rightly deserved both.

In 1891 Franklin Leonard Pope, a charter member of the AIEE who became its president in 1884, wrote a series of five articles for *The Electrical Engineer* entitled: "Inventors of the Electric Motor." Although the title carried the word "inventor" in the plural, he proved conclusively that Thomas Davenport alone was the inventor of the electric motor. His evidence can be considered to be most trustworthy since he had opportunity to converse with living witnesses and examine original documents. On February 24, 1891, exactly 54 years, less a day, after Davenport had received his patent on the electric motor, Pope read a paper before a meeting of the AIEE in which he sought "to rescue from impending oblivion the true story of the invention of the electric motor." But now, more than 110 years since United States Patent number 132 was issued, the dark-

THOS. DAVENPORT, OF BRANDON, VERMONT.

IMPROVEMENT IN PROPELLING MACHINERY BY MAGNETISM AND ELECTRO-MAGNETISM.

Specification forming part of Letters Patent No. 139, dated February 25, 1837

To all whom it may concern:

Be it known that I, THOMAS DAVENPORT, of the town of Brandon, in the county of Rutland, State of Vermont, have made a discovery, being an Application of Magnetism and Electro-Magnetism to Propelling Machinery, which is described as follows, reference being had to the annexed drawings of the same, making part of this specification.

The machine for applying the power of magnetism and electro magnetism is described as follows:

The frame A may be made of a circular or any other figure, divided into two or more platforms, B and C, upon which the apparatus rests, of a size and strength adapted for the purpose intended.

The galvanic battery D is constructed by placing plates of copper and zinc E and F, alternately of any figure, in a vessel of diluted acid, G. From each vessel are two conductors, H and I, one from the copper and one from the zinc, leading to and in contact with copper plates K and L placed upon the lower platform. These plates or conductors are made in the form of a segment of a circle corresponding in number with the artificial magnets hereinafter described, placed around the shaft detached from one another and from the shaft, having a conductor leading from the copper plate of the battery to one of said plates on the lower platform, and another conductor leading from the zinc plate of the battery to the next plate on said lower platform, and so on alternately (if there be more than two plates on said lower platform) around the circle.

The galvanic magnets M N O P are constructed of arms or pieces of soft iron in the shape of a straight bar, horseshoe, or any other figure, wound with copper wire Q first insulated with silk between the coils. These arms project on lines from the center of a vertical shaft, R, turning on a pivot or point in the lower platform, said copper wires Q extending from the arms parallel, or nearly so, with the shaft, down to the copper plates K and L and in contact with them. The galvanic magnets are fixed on a horizontal wheel of wood, V, attached to the shaft.

The artificial magnets S T are made of steel and in the usual manner. They may be of any number and degree of strength and fixed on the upper platform, being segments of nearly the same circle as this platform; or, if galvanic magnets are used, (which may be done,) they may be made in the form of a crescent or horseshoe, with their poles pointing to the shaft. Having arranged these artificial magnets on the top of the upper circular platform, there will be a corresponding number of magnetic poles, the north marked 5 and the south pole 6. Now, we will suppose the machine to be in a quiescent state. The galvanic magnet No. 1 being opposite the north pole of the artificial magnets, the galvanic magnet No. 3 will, of course, be opposite the south pole No. 6, and the galvanic magnets Nos. 2 and 4 will be opposite each other, between the poles just mentioned. There being a corresponding number of copper plates or conductors placed below the artificial magnets around the shaft, but detached from it as well as from each other, with wires leading from the galvanic magnets to these plates and in contact with them, as before described, these wires will stand in the same position in relation to the copper plates that the galvanic magnets stand to the artificial magnets, but in contact with the plates.

Now, in order to put the machine in motion, the galvanic magnet No. 2, being changed by the galvanic current passing from the copper plate of the battery along the conductors and wires, becomes a north pole, while at the same time the magnet No. 4 is changed by the galvanic current passing from the zinc plate of the battery, and becomes a south pole. Of course the south pole of the artificial magnet No. 6 will attract the north pole of the galvanic magnet No. 2 and will move it a quarter of a circle. The south pole of the galvanic magnet No. 4, being at the same time attracted by the north pole No. 5, and the south magnet No. 4 also to perform a quarter of a circle. The momentum of the galvanic arms will carry them past the centers of the poles Nos. 5 and 6, at which time the several wires from the galvanic magnets will have changed their positions in relation to the copper plates or conductors. For instance, the north pole No. 2 having now become a south pole by reason of its wire being brought in contact with the conductors of the zinc plate, and No. 4 having in like manner become a north pole, its wire having changed its position from the zinc plate to the copper plate, the poles of the galvanic magnets are, of course, now repelled by the poles that below attracted them, and in this manner the operation is continued, producing a rotary motion in the shaft, which motion is conveyed to machinery for the purpose of propelling the same.

The discovery here claimed, and desired to be secured by Letters Patent, consists in—

Applying magnetic and electro magnetic power as a moving principle for machinery in the manner above described, or in any other substantially the same in principle.

FACSIMILE OF THE ORIGINAL PATENT

ness of that oblivion seems to have engulfed the accomplishments of this early American inventor. It would seem fitting that, at this time, some lasting tribute be made to perpetuate the memory of Thomas Davenport. Throughout the history of our electrical science fitting honor has been bestowed upon such men as Alessandro Volta, Andre-Marie Ampere, Georg Simon Ohm, James Watt, Joseph Henry, Michael Faraday—such that their names are of common usage in the classroom and in industry. Would it not seem appropriate that Thomas Davenport be honored in a similar manner? Could not the unit of performance of rotating engines, the horsepower, which is used so much in connection with electric motors, be changed to "davens," in honor of the inventor? What procedure must be followed to effect such a change, I do not know, but an expression of our tribute to this almost forgotten American seems to be wanting, and the opportunity to change this archaic term may present the occasion to bestow this belated honor.

No Discussion

Facsimile Transmission for Pickup and Delivery of Telegrams

G. H. RIDINGS
NONMEMBER AIEE

As the tempo of progress in science, industry, transportation—in every field of human endeavor—increases with each passing day, so, too, does the demand for swifter, less expensive, and more convenient methods of record communication, for it is usually by record communication that the various steps of any important project are undertaken. Business men and banks rely upon some form of record communication for the execution of orders, contracts, loans, for expediting sales and deliveries, for the presentation of statements, in fact, for nearly every business transaction. So, too, do most organizations in transportation and allied fields, news gathering and law enforcement agencies, and the various agencies of government. It is essential that progress in record communications keep pace with that in other fields.

We are keenly aware of the tremendous progress made in the field of transportation, from the early days of the stagecoach and covered wagon. Although somewhat less spectacular, the extent of progress in record communications over the same period of time has not been less notable. From the days of the key and sounder, with its many manual retransmissions, and relatively few miles of pole lines subject to the whims of the elements, the industry has progressed through the inventions of the duplex, the printing telegraph, and the multiplex to the vast carrier system networks of today, with the varioplex, and push-button and automatic switching to provide the utmost in swift, efficient service. The necessity for manual retransmission is greatly reduced and well on the way to being eliminated. The number of communication channels has been increased manyfold and circuit interruptions minimized. The radio-beam networks now being installed are still further increasing the number and quality of communication channels and should go a long way towards eliminating circuit interruptions due to weather and atmospheric conditions.

While great strides have been made in recent years in intercity handling of telegrams, the problems of intracity, or terminal handling, have not been overlooked. Business organizations have been provided with teleprinters having features especially designed for their particular needs including direct connection with a Western Union central office. Where the volume of business is both large and concentrated, direct-wire connections are provided; with lesser volume of a concentrated nature, telemeter service provides an efficient, direct, service facility. Both services include teleprinters. The newest development in this field is the "Telefax" employing facsimile principles. It eliminates keyboard transmission, and since it is essentially a reproductive process, the opportunity for error is removed. Telefax has already received the thorough test of in-plant and customer use. Circuit concentrators were developed to meet Western Union central-office requirements. Customer enthusiasm has encouraged the company to embark upon a program of expanding this type of patron connection to include business offices, hotels, transportation terminals, apartment houses, and similar locations.

Terminal Handling for the Small Account Customer

Where terminal handling facilities of the type already described can be made available, the time and cost incident to messenger pickup and delivery are eliminated. However, volume and equipment costs are all important considerations in substituting mechanical for physical terminal handling methods. Today the simplest teleprinter represents a sizeable investment which, together with operating and maintenance charges, make it uneconomical to employ such equipment where telegraph volume is comparatively light. While the cost of Telefax equipment was lower, and it afforded more reasonable operating and maintenance charges, the initial cost of such equipment was still too high to permit of widespread use in the moderate volume field. Obviously, it became essential to lick this problem of economics if we were to capture the sales and service value of direct-service methods for the user with moderate volume. This terminal handling problem assumed even more importance as Western Union mechanized its internal operations and eliminated manual retransmission in a relaying process. Too often, the service advantage thus accomplished was in great measure offset by the delay inherent in messenger delivery.

What, then, were the steps to be taken to make it economically practical to provide an efficient pickup and delivery medium for users whose volume requirements did not justify expensive teleprinter equipment? In the order of importance they are:

1. To develop some form of pickup and delivery device whose initial cost and operating and maintenance charges are so low that it may be economically employed to provide a direct-wire connection to the nearest Western Union central office for the many thousands of small businesses whose use of the telegraph is not sufficiently frequent to justify expensive printer terminal equipment.

2. To develop automatic or semiautomatic pickup and delivery devices which may be installed in every large office building, apartment house, and hotel, whereby tenants

Paper 48-233, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted February 16, 1948; made available for printing September 10, 1948.

G. H. Ridings is assistant Telefax research engineer with the Western Union Telegraph Company, New York, N. Y.

Figure 1. Telefax transmitter-recorder with optical scanning

could secure most of the benefits of a direct connection to the Western Union central office, even though their individual use of the telegraph might be infrequent. These installations would be, in effect, miniature Western Union branch offices.

3. To provide, for residential areas, automatic, conveniently located, pickup devices and Telecars for delivery. These Telecars are automobiles equipped with Telefax recorders having direct, radio connection to the Western Union central office.

It should be noted that all three phases of this program require the development of simple, inexpensive, easy to operate, automatic or semiautomatic machines. In addition, these machines must be sturdy and require a minimum of maintenance. No process which requires that the intelligence be transcribed into a code for transmission could be employed in the design of equipment sufficiently automatic for the purposes outlined before. And, of course, no process involving the transcribing of the human voice could be considered sufficiently safe because there would be no opportunity, with mechanical recording, to verify imperfections. The requirements can only be fulfilled by employing some sort of facsimile process wherein the telegram is treated as a unit rather than as a series of units.

What Has Already Been Accomplished

Progress has already been made towards the goal previously outlined. The basic ground work has been laid and future progress should be at a rapid rate. For one thing, a record sheet called "Teledeltos" has been developed by Western Union and its use under widely varying conditions, both in telegraph service and in equipment employed by our armed forces during the war, has shown it to be entirely satisfactory for these purposes.

"Teledeltos" is a dry recording paper which, unlike most recording media, requires no processing of any kind before or after recording. The coating of this conducting paper is light in color and turns black when electric current of about 20 milliamperes passes through it. Either alternating or direct current may be employed in recording. The paper is sensitive only to electrical impulses and is affected by light or moisture much less than is ordinary writing paper. It produces a clear-cut and permanent record with no "fixing" of any kind required. There is no apparent ageing of records many years old. Teledeltos is extremely fast, pulses of 0.0001 second duration being easily recorded. It is capable of reproduction speeds many times the highest yet employed in commercial, facsimile equipment. Its current density characteristic is such that fairly good half-tone reproduction may be obtained if desired, without special circuit arrangements. Its cost is a small fraction of the cost of photographic paper. Only the simplest of recording equipment is needed. Amplified tone signals, without rectification, may be applied directly to the paper by means of a stylus riding continuously on its surface.

A number of different types of automatic and semiautomatic transmitters, transmitter-recorders and recorders have been developed and employed commercially on a limited scale for the pickup and delivery of telegrams. Among these is the transmitter-recorder shown in Figure 1, designed for use in a patron's office. It is about the size and shape of a teleprinter or typewriter. This machine may be placed on a table or desk or may be furnished complete with a pedestal. The machine is 11 inches high, $16^1/_2$ inches wide, and $15^1/_2$ inches deep. It is self-contained, requiring only the line pair, a ground, and a source of 110-volt 50-to-60-cycle alternating current for its operation. This machine has three controls: a send-receive switch, a vernier control for adjusting the density of the recorded copy; and a starting switch. To transmit a telegram, it is wrapped by hand around the drum which protrudes from one side of the cover. The send-receive switch is set to "send" and the starting switch operated. Thereafter, operation is entirely automatic. A call is set up in a concentrator at the central office. There, a switching unit in which the patron's lines terminate automatically connects an idle recorder to the circuit and the message is recorded. After the message has been completely scanned, the patron's machine shuts down automatically.

Figure 2. Automatic Telefax transmitter

To transmit a telegram from the central office to a patron, the attendant wraps the message about a drum and inserts it into one of several transmitters which are a part of the concentrator. The operator then connects the transmitter to the patron's line, causing a buzzer to sound summoning him to his machine. The patron places a sheet of Teledeltos on the drum, sets the send-receive switch to "receive," and operates the "start" switch. Transmission starts immediately and automatically. When the message has been recorded and the transmitter stopped, a red signal lamp on the top of the patron's machine will light and the patron may stop the machine and remove the telegram. If the patron does not stop the machine it will continue to scan until the entire blank has been scanned, at which time it will shut itself off automatically. If, in sending or receiving a message, the send-receive switch is inadvertently placed or left in the wrong position, the red signal lamp will light, and transmission will not start until the switch is operated correctly.

Another development is the transmitter shown in Figure 2 designed to facilitate the pickup of telegrams in office buildings,

apartment houses, hotels, and similar locations. In this equipment we have taken another step towards the goal of a completely automatic telegraph system. With these machines it is as easy to file a telegram as it is to mail a letter. The customer or agent simply presses a button and drops the telegram into the slot in the front of the machine. This is all that is required of him. The telegram automatically wraps itself about the drum of the transmitter and the entrance to the slot closes, preventing the insertion of another telegram until the first one has been transmitted. Several of these machines may be operated over one line pair where the volume of business is light. Circuits from these transmitters terminate in a central office in a facsimile receiving concentrator, from which all of the functions of the transmitter are controlled. After the message has been recorded at the central office, the telegram is stripped from the drum of the transmitter and deposited into a receptacle beneath the drum, and the transmitter released.

Two types of transmitters are employed in this service. One is a wall model about 30 inches high, 15 inches wide, and 8 inches deep. The other, illustrated in Figure 2, is a table model, 24 inches high, 16 inches wide, and 12 inches deep. This model may be equipped with a pedestal, if desired, so that it will rest directly on the floor. Both machines are completely self-contained requiring only a line pair, a ground, and a source of 110-volt 50-60 cycle alternating current for their operation. Where an agent is employed to operate it, the machine is equipped with a push-button for starting. Where it is to be installed for unattended service, in an office building lobby for example, it may be equipped with a lock switch and charge account patrons in the building supplied with keys. In the case of the unattended installation in a public place, a coin-slot mechanism may be employed.

Figure 4. Schematic view of scanning mechanism of Desk-Fax transceiver

Figure 3 illustrates an automatic, Telefax recorder employed in the Telecar delivery service referred to previously. This recorder, which is controlled by radio from the central office, employs a roll of Teledeltos, from which a length sufficient for one message is automatically formed into a cylinder and scanned internally, then cut from the roll and ejected from the front of the recorder. The process is automatic, and while the operator of the car is delivering one telegram, another is being recorded and deposited into the convenient receptacle just under the dash of the car. Radio and control equipment are located in the trunk of the car.

Radical Changes in Design Necessary to Lower Equipment Cost

When the patron's transmitter-recorder shown in Figure 1, was developed, it was expected that it would answer the service requirements of a large majority of small businesses. The results of the limited installations which have been in service through the war years have been highly satisfactory. However, post-war economic conditions have made it necessary to develop a much simpler and cheaper machine to serve a larger portion of the Telegraph Company's patrons, particularly those in the small business category, and thus make possible nationwide expansion of patron Telefax service.

To undertake such a development, it was necessary to think along radically different lines than heretofore. Conventional methods of scanning, line-feed, and so forth, had to be discarded. The simplest means of facsimile recording is that wherein the facsimile signals are applied directly to a stylus riding continuously on the surface of an electrosensitive record sheet, and having such a record sheet in Teledeltos, this method of recording was chosen for our transceiver. Now, it was reasoned, that if some form of conductive pickup could be employed, this same stylus could be utilized to scan

Figure 3. Telefax recorder for mobile delivery of telegrams

Figure 5. Desk-Fax transceiver—cover removed

the subject copy and a really simple transceiver would result. Why not use conductive pickup? The principle is sound, as old as facsimile itself. True, good half-tone characteristic is impossible, but for message transmission it is not necessary.

What about the preparation of subject copy? The use of conductive pickup simply means furnishing patrons with a different kind of blank than would be provided for use with some other type of transmitter, since it is accepted practice to provide the customer with blanks upon which to prepare his telegrams.

The problem then resolved itself, for the most part, into the development of a simple, economical, easy-to-use sending blank upon which writing and typing would have a different conductivity from the blank itself. Two methods for the preparation of subject copy have been developed which give satisfactory results. One method employs a sheet of Teledeltos, similar to that which is used as the record sheet. Over this is placed a sheet of special carbon paper, and writing or typing on the back of the carbon paper transfers the electrically conducting carbon onto the surface of the Teledeltos. The carbon penetrates the thin insulating coating of the Teledeltos, making contact with the conductive base of the paper. A stylus scanning such a subject copy would traverse characters of low resistance whereas the background of the paper would present an extremely high resistance—practically open circuit.

The second method employs a sheet of black conducting base stock which is ordinarily coated to form Teledeltos. This method also involves the use of a special carbon paper. In this case the so-called carbon paper is coated with a white insulating wax so that writing or typing on its reverse side transfers white insulating characters to the black conducting paper. A stylus traversing this subject copy would encounter characters of very high resistance—practically open circuit—whereas the background of the paper would present a fairly low resistance. Having such a subject copy, it is a simple matter to use it to key or modulate the output of a vacuum-tube oscillator. With the aid of a bridge arrangement it is equally easy to provide for signal conversion so that with a simple adjustment a "positive" or a "negative" may be transmitted from either of the two types of subject copy.

Mechanically, also, our transceiver must be made as simple as possible. The simplest scanning mechanism consists of a drum rotated at constant speed upon which is mounted the subject copy or record sheet, while the scanning point or stylus is caused to move at a uniform rate along the length of the drum. Of course, the same relative motion could be secured by causing the drum to move along its axis as it rotates, with the scanning point remaining fixed in space, but the former method is employed in this transceiver. Conventionally, this relative motion, or line feed, is secured by means of a feed-screw and half-nut, but, in our transceiver, it is accomplished by winding up a cord on a drum or reel powered by a small clock motor. The reel is frictionally coupled to the motor shaft so that the stylus housing may be manually returned to the "start" position after the completion of each transmission. A slotted, tubular track is provided to support and guide the stylus housing, with the slot fashioned in such a manner as to cause the stylus housing to be raised from the drum in the "start" position to facilitate loading. Figure 4 shows schematically how this is accomplished. The cord which is attached to the stylus housing at the pin projecting through the slot in the tube passes over the pulley at the right end of the tube and then back again through the tube to the reel on the clock motor shaft at the left of the machine. The motor causes the stylus housing to feed to the right, and it is returned manually by pushing it towards the left at the end of transmission. The pin riding up the incline in the tube slot at the extreme left lifts the stylus housing to a vertical position. The stylus holder is a replaceable unit to facilitate renewal, and the stylus itself is pivoted so that when the stylus housing is in an upright position the stylus is completely withdrawn into the housing. Pivoting the stylus also prevents damage to this vital part of the mechanism if the patron should improperly remove a blank from the drum without first returning the housing to the "start" (upright) position.

Mechanism of the New Transceiver

Figure 5 is a close-up of the mechanism of the transceiver. The subject copy or record sheet is held on the drum by the flange at its left end and by a toroidal spring which is rolled onto it from the right end. A small, synchronous motor mounted on the rear of an L-shaped bracket drives the drum through a single set of gears, and a simple, fabric brake on the drum shaft takes up any back-lash. On the drum shaft is a commutator which is used for phasing. Above the drum motor, on top of the bracket, is the small clock motor with frictionally coupled reel which causes the stylus housing to move out along the tube parallel to the drum. At the extreme right end of this tube is a sleeve which is connected by means of a rod extending through the tube back to a "start-stop" switch mounted on top of the bracket. This sleeve which is operated manually to the left to start the transceiver will be moved to the right or "off" position by the motion of the stylus housing as it completes the scanning of the message blank. This mechanism is shown diagrammatically in Figure 4.

The controls of this transceiver are simpler than those of the larger machine of Figure 1. Both machines employ a "start-stop" switch which serves also as an end-of-message switch, but this newer transceiver does not have a send-receive switch nor a control to regulate the density of the recorded copy. In this transceiver, operation of the "start" switch automatically sets up the machine as a transmitter unless a call has been placed at the central office causing the buzzer to operate in the patron's machine. Under these conditions, operation of the "start" switch automatically sets up the transceiver as a recorder.

Since the circuits from these transceivers may terminate in large concentrators at the central office, the use of number sheets there would be extremely cumbersome. Provision is therefore made for the patron to acknowledge individually the receipt of each telegram. This is accomplished by means of a small neon lamp (which, together with the buzzer, indicates to the patron the completion of a transmission to him), and a push-button which he operates after reading the received message.

The mechanism is assembled from simple stamped and bent sheet metal parts and die castings wherever possible, with a minimum of machined parts, most of which are of the screw-machine variety. The drum and stylus-feed motors, gears, "start-stop" switch and stylus connector are inexpensive commercial items. There are no close tolerances, and the stylus construction is such that considerable eccentricity of the drum may be tolerated. The entire mechanism mounts on the L-shaped bracket and may be assembled or disassembled in a very few minutes with no special tools. There are few adjustments, none critical.

Electronics and Control Circuits—Characteristics

The mechanism mounts across the front of a sheet-metal chassis which contains the electronics and control circuits.

Figure 6. Top view of Desk-Fax transceiver, showing layout of parts

Figure 7. Bottom view of Desk-Fax transceiver, showing accessibility of components

Wiring of the mechanism terminates on convenient terminal strips on the chassis to facilitate servicing or replacement. Figure 6 shows the complete unit with cover removed and Figure 7 shows the under side of the chassis with bottom plate removed. Although the chassis measures only $10^1/_8$ by $11^1/_8$ inches, there is no crowding of parts, and relays, vacuum tube sockets, terminal strips, and other vital components are readily accessible for test or maintenance purposes. The electronic circuits employ four tubes, a rectifier for power supply, a dual triode which serves as oscillator and transmitting amplifier, and a high-mu pentode and a power output tube which serve as the recording amplifier. The use of separate tubes for transmitting and recording would appear an extravagance, but such is not the case. By switching tubes from one circuit to the other, at most, one tube would be saved the cost of which is more than outweighed by the simplification of switching and wiring which the use of separate tubes permits.

Controls are provided for transmitting and recording levels and for bridge balancing. These are set for each installation and remain unchanged unless servicing is required. A terminal strip is provided for attaching line wires and ground, another for attaching a rubber-covered power cord so that the desired length of cord for each installation may be provided. With the exception of the oscillator coil, all components of the electronic and control circuits are inexpensive, commercial items. The power transformer is similar to that used in the smallest a-c table-model radios. A transformer couples the amplifier to the line pair, serving as an output transformer when transmitting and as an input transformer when recording. Control relays are the inexpensive, rugged type employed in juke boxes and pinball machines. No critical adjustments are required. The relays are mounted so that the contacts are accessible for cleaning. Wiring of the unit is comparable to that of a small table-model radio and can be done in economical assembly-line fashion. The over-all dimensions of the transceiver, with cover and blank holder, are $11^1/_8$ inches by $11^1/_4$ inches by 7 inches. It weighs about 19 pounds. Maximum power consumption is 100 watts, and no power is consumed when the machine is idle.

The oscillator frequency is about 1,900 cycles and a total band width of 1,900 cycles is adequate so that the transceiver will operate over an ordinary telephone pair. The 2-inch drum rotates at 180 rpm and the line feed is 125 lines per inch to match the index of cooperation of the central office equipment which employs a larger size blank. Blank size is $6^1/_2$ inches by $4^1/_2$ inches with a useful message area of $5^3/_8$ inches by 3 inches. This will accommodate about 150 typewritten words and is transmitted in two minutes. No special provisions for synchronization are made, the synchronous driving motor being operated from the same commercial 50 or 60 cycle a-c power source employed at the central office. Phasing, signalling, and other necessary control functions operate on a d-c basis using the physical wires with ground return through a center-tapped primary of the line coupling transformer. Phasing clutches on the central office transmitters and recorders are controlled by the commutator of the patron's machine.

Central-Office Equipment—Circuit Operation

Circuits from these transceivers terminate in Western Union central offices in concentrators made up in multiples of 50-patron units. Each 50-patron unit is provided with four conventional telegram-size optical transmitters and six conventional-size page-type continuous recorders. The transmitters employ the so-called color-sensitive photocell and improved electronics so that messages received by tape printer, page printer, and various other means may be transmitted with equal fidelity.

To send a message to a patron, the central-office operator wraps the message about a drum, inserts the drum into a transmitter and plugs up to that patron's circuit. This removes positive, standby

Figure 8. Desk-Fax transceiver with stylus scanning for transmitting and recording

potential and applies negative potential to the line over the simplex circuit which operates a relay in the patron's transceiver, causing the buzzer to sound. When the patron answers the call by loading his drum with a Teledeltos recording blank and operating the "start" switch, the buzzer stops and the transceiver is automatically set up as a recorder. As soon as the transceiver's tubes heat up, a relay operates to start the stylus-feed motor and to send out phasing pulses (interruption of the direct current over the simplex loop). The central-office transmitter phases immediately and the transmission of the message proceeds. When the message has been transmitted, the transmitter stops and polarity of the battery on the line is reversed causing the acknowledge lamp and buzzer to operate in the patron's transceiver. After the patron has examined the recorded message he operates the acknowledge push-button which extinguishes the light, stops the buzzer and opens the simplex loop giving an acknowledgment indication to the central-office operator. The operator then removes the transmitter from the line.

To send a message to the central office, the patron wraps the subject copy, prepared as described previously, about the drum and operates the start switch. This sets up the transceiver as a transmitter and operates a relay at the central office which gives appropriate indication to the operator that a call from that patron is waiting, who then connects a recorder to the calling circuit and operates a start button. As soon as the heat relay of the transceiver has operated, the recorder phases from the first phasing pulse from the transceiver's commutator. Contacts on the phasing relay reverse the potential on the line which starts the stylus-feed motor at the transceiver. Transmission continues until the transceiver shuts down automatically or until the patron manually operates the "start-stop" switch. The recorder stops also, and a light indicates to the operator that the message is complete, who then rotates a paper-feed-out knob on the recorder until the conventional telegram-blank length of paper is fed out, at which time the light is extinguished. The message is then torn off and the recorder disconnected.

The first concentrators for this service will be of the plug-and-jack manual type, the switching turret resembling the familiar PBX switchboard. Circuits have been worked out for a more automatic concentrator with automatic line finders on the receiving side and push-button switching on the sending side, should this method of operation be found desirable. At the present time there is some question as to the economy of such operation since a certain amount of manual attention is necessary in any event for checking, acknowledging, and other functions involved in transacting business directly with the patron.

A New Patron-to-Patron Transceiver

A machine similar to this transceiver has been developed for patron-to-patron use. That is, two machines work together directly without any central office concentrator equipment. The same mechanism is employed with some rearrangement of the control circuits and a simple phasing circuit whereby one motor drifts into step with the other. Phasing is accomplished without the use of conventional magnets or clutches, employing the commutator on each motor shaft and an added capacitor which is connected across the recorder driving motor, causing it to run slightly under synchronous speed until pulses from the two commutators are in step, at which time the capacitor is removed and both motors run synchronously. Such machines may be used to provide intercommunication for business organizations or for pick-up and delivery of telegrams where only a few patrons are involved and a concentrator is not justified.

Installations of the type just described have been in operation in one of our eastern cities for the past several months from which considerable information has been obtained that has been helpful in improving the design. A number of ways were found to simplify and improve the mechanism, and the mechanical and electronic portions which were originally separate units are now combined into one, permitting a sizeable reduction in manufacturing costs. The trial installations have shown this method to be quite satisfactory for pick-up and delivery of telegrams. Reports are that patrons have found it to be so convenient that their use of the telegraph has substantially increased since they were provided with this facility.

Two thousand transceivers, incorporating all of the improvements resulting from these trial installations, are now being manufactured. The manufacturing cost of this unit is expected to be about one-third that of the larger patron's machine of Figure 1. Central-office concentrator equipment is being manufactured for installations in six major cities. Although over 1,000,000 telegrams a year are handled by facsimile equipment, these new installations will increase the volume of telegraph traffic handled by facsimile principles manyfold and should pave the way for still larger installations in the future, particularly for small volume telegraph users.

While this simple low-cost transceiver cannot be regarded as the ultimate in record communications any more than Ford's Model T was the ultimate in transportation, we believe that it will answer a corresponding need in an equally creditable manner.

An Automatic Standing-Wave Indicator

PHILIP J. ALLEN
NONMEMBER AIEE

WITH microwave standing-wave measurements in the laboratory becoming as commonplace as sewing in the home, it is not surprising that the hand-operated travelling probe should soon develop into a "sewing machine." This paper describes an X-band (3-centimeter) automatic standing-wave indicator in use at the Naval Research Laboratory which has cut to a fraction the time required to make standing-wave measurements, and not only reduces the tedium accompanying the usual routine, but actually adds interest to the task. The apparatus reproduces the standing-wave pattern on a cathode-ray tube, and measurements are made directly from calibrated scales. This type of presentation allows unusually rapid adjustment of radio-frequency components, since the effects of adjustments are apparent instantly. A number of novel techniques are thereby made possible.

Impedance measurements at microwave frequencies generally are made relative to some reference impedance, usually the characteristic impedance of the transmission line. The problem of determining impedance by means of standing-wave measurements involves the determining of two factors: the standing-wave ratio in the transmission line (conveniently the ratio of the maximum to minimum voltage amplitude); and the phase or position of the voltage minimum relative to a point of known impedance. This known impedance is most conveniently made zero by placing a short circuit at a known position in the transmission line. Conventionally, these measurements are made with a manually-operated, travelling probe which samples the r-f field along the line, and by means of a detector and auxiliary equipment, usually an amplifier and indicating meter, the ratio of voltage maximum to voltage minimum is obtained. The relative position of the voltage minimum is determined by converting the linear displacement of the probe into an equivalent angle, or wave-length fraction. When the standing-wave ratio and the relative position of a minimum of the standing-wave pattern have been determined, the desired impedance can be found, using transmission line equations, or some form of circle diagram or impedance chart. Thus, for rapid determinations of impedance, the values of standing-wave ratio and relative location of the voltage minimum must be readily obtainable.

In the event that it is sufficient to know only the magnitude of the reactance of a component being tested, the task is reduced to one of determining the standing-wave ratio alone. In still other instances, it is sufficient merely to adjust a component for minimum standing-wave ratio for best "match" to the transmission line, without actually making a quantitative determination. However, even this operation can become a task if numerous determinations have to be made, as is usual when a component is being adjusted for optimum match to the transmission line. In many such instances, the time required to determine the effect of an adjustment is frequently much greater than the time required for the adjustment itself, with a consequent inefficient use of time. Thus, a method which provides an instantaneous indication of the effect caused by adjustment can reduce over-all adjustment time considerably.

The automatic standing-wave indicator was developed with these several considerations in mind, and consists of a specially-designed reciprocating probe, a conventional high-gain audio amplifier, and a special indicator employing a long-persistence cathode-ray tube. In operation, a pictorial representation of the standing-wave pattern in the transmission line is reproduced on the cathode-ray tube, and from this picture, the voltage standing-wave ratio (VSWR) and relative phase of the standing-wave pattern may be quickly and accurately read from calibrated scales.

The r-f bench setup for use with the automatic standing-wave indicator differs little from the conventional arrangement. In place of the usual manually-operated, travelling probe, there is a motor-driven, reciprocating probe, and the usual indicating meter at the amplifier output is replaced by a calibrated cathode-ray indicator. A typical test setup employing the automatic standing-wave indicator and a minimum of microwave equipment is shown in Figure 1. The waveguide components include a *2K25* klystron signal source, attenuator pad, calibrated wavemeter, variable attenuator, reciprocating probe, and a crystal detector termination. Behind the wave-guide equipment, the high-gain amplifier rests on top of the klystron power supply and modulator. To the right, is the cathode-ray indicator used for reading both standing-wave ratio and phase of the pattern. As most of the components of the setup are conventional, only the special units of the automatic standing-wave indicator will be described.

The Reciprocating Probe

Basically, the reciprocating probe is similar to the conventional slotted-line probe having adjustable probe depth and matching facilities for the crystal detector. Although there is still provision for manual operation of the probe, a 100-rpm motor, flywheel and connecting rod have been added to make it travel automatically back and forth along the slotted line over a distance slightly greater than one guide wave length. As the probe moves, a pair of contact fingers mounted on an insulating block attached to the moving

Paper 48-234, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted July 20, 1948; made available for printing August 25, 1948.

PHILIP J. ALLEN is with the Naval Research Laboratory, Anacostia, D. C.

probe wipe along two wire-wound linear resistor strips mounted below and parallel to the waveguide. These resistors are cross-connected and supplied with an adjustable d-c voltage. This arrangement, which may be seen in Figure 2, is used to generate a push-pull horizontal sweep voltage for the cathode-ray indicator. The lateral position of the spot on the indicator thus is made to correspond to the position of the probe along the transmission line. When the equipment is functioning without a vertical signal applied to the indicator, the spot on the cathode-ray tube moves back and forth with the reciprocating probe, drawing a straight horizontal base line. The output of the probe crystal detector is fed through the high-gain amplifier, and connecting the amplifier output to the vertical deflecting plates of the indicator results in a picture of the standing-wave pattern in the transmission line.

The Amplifier

A number of good high-gain amplifiers, some employing a parallel-T feed-back network, intended for standing-wave measurements are commercially available, and most of these can be adapted readily, with slight modification, for use with the automatic standing-wave indicator. These amplifiers are usually equipped with a built-in output meter and rectifier, but may not have provision for obtaining the necessary audio output. With the amplifier being used, the only modification necessary was the installation of an audio output jack, the available output voltage being more than adequate for the vertical deflection desired. To get maximum output voltage, the amplifier is operated with the interior–exterior meter switch in the exterior position. This reduces wear and tear on the output meter, since the amplifier is operated at a higher output level than when used normally with the internal meter.

The Indicator

It is desirable and important that the interpretation of the standing-wave indications be as simple and convenient as possible, and, at the same time, allowing maximum utility of the automatic standing-wave indicator. For this reason, the presentation is in the form of a visible standing-wave pattern, from which variations in standing-wave ratio and phase can be continuously observed. A long-persistence cathode-ray tube is used for the presentation since the horizontal sweep generated by the probe takes place only 200 times a minute. The vertical sweep frequency is that of the klystron modulator and may be several hundred cycles per second.

The indicator unit, shown in Figure 3, houses the high-voltage power supply for the cathode-ray tube and a gas-tube-regulated 300-volt d-c supply used for the bias on the horizontal sweep-generating resistors. A wire-wound potentiometer for adjusting horizontal sweep amplitude permits varying the voltage applied to these resistors from zero to the full 300 volts.

A rectangular lucite scale, about three inches wide and located in front of the cathode-ray tube, is calibrated with engraved horizontal lines which are used to indicate directly the VSWR of the normalized standing-wave pattern appearing on the cathode-ray tube. This scale shown in Figure 4, is mounted on a gear-driven rack controlled by the dial in the center of the indicator panel which allows the scale to be moved manually across the face of the indicator tube. The width of the scale and the size of the gear have been chosen so that in one revolution of the dial, the scale travels laterally across the face of the cathode-ray tube a distance equal to the scale width. The movable scale and dial are used for indicating the phase shift of the standing-wave pattern on the transmission line. The dial is calibrated in either degrees, radians, or decimals of wave length, depending on the application.

Although the a-c output of the amplifier produces a symmetrical wave form possessing a "modulation envelope" representing the standing-wave pattern, only the positive half of the pattern is used. An adjustable, vertical-centering voltage applied to the cathode-ray tube shifts the center of the symmetrical pattern to the position of the base line shown in the patterns of Figure 4, and "clipping" of the bottom half of the symmetrical waveform is accomplished with a strip of black masking tape stretched across the lower part of the cathode-ray tube face.

The motor on the reciprocating probe is controlled by a switch on the indicator panel which actuates also a relay to remove the spot from the cathode-ray tube to avoid burning the screen whenever the probe is not operating.

Operation

With standing waves existing in the transmission line, and the reciprocating probe operating, a standing-wave pattern similar to one of those shown in Figure 4 appears on the indicator. To read the VSWR it is necessary only to normalize the pattern by adjusting the variable r-f attenuator or the amplifier gain until the maxima of the standing-wave pattern are tangent to the top horizontal line on the scale. The VSWR is then read as the value associated with the horizontal line

Figure 1. (below) Typical setup employing automatic standing-wave indicator

Figure 2. (right) Rear of reciprocating probe showing sweep-generating resistors

Figure 3. Standing-wave indicator

passing tangent to the minima of the pattern. Slight visual interpolation may be necessary.

When determinations of the relative phase of the standing-wave pattern along the transmission line are to be made, the horizontal sweep amplitude is adjusted until one edge of the movable scale and the vertical center line coincide with adjacent minima of the standing-wave pattern. This adjustment can be made most accurately with a high standing-wave ratio in the transmission line. Holding the scale in this position with the knob, the dial, which is friction-coupled to the knob, is set to read zero. With this done, any shift in the standing-wave pattern along the transmission line can be found by resetting the knob until the edge and center of the scale again coincide with the same minima. The shift and its direction is indicated directly by the dial, which may be calibrated in degrees, radians, or decimal parts of a wave length.

Features and Applications

With the travelling probe operating automatically, and a continuous picture of the standing-wave pattern appearing on the screen of the indicator, a number of unusual advantages of the instrument become apparent. One hand has been freed from the task of manipulating the travelling probe and thus is available for other operations or adjustments. With the cathode-ray tube indicator, the VSWR is found more conveniently, and as accurately, as with the meter used usually for this purpose. In addition, no difference computations and conversions are required to determine the amount of shift of the standing-wave pattern, since this can be read directly from a dial, the calibration of which is independent of the actual wave length. In addition to the rapidity with which measurements or adjustments on components can be made, the fact that the device is active actually adds interest to the measuring process.

One of the simplest yet perhaps the most valuable applications of the automatic standing-wave indicator is found in its qualitative picturing of the effects on the standing-wave pattern caused by changes or adjustments made to line components or terminations. The results have to be seen to be fully appreciated, but a description of typical examples will have to suffice here. For instance, the adjustment of a termination for optimum standing-wave ratio with the automatic standing-wave indicator can be accomplished often in a matter of seconds. The effect of adjustments is immediately seen on the cathode-ray indicator, and adjustments are carried out in the direction of lessening standing-wave ratio until a matched condition is reached or most nearly approached. The standing-wave

(A). VSWR of 2.0

(B). VSWR of 1.4

(C). VSWR of 1.1

(D). VSWR of 1.0

Figure 4. Typical standing-wave patterns

patterns progress from the stage shown in Figure 4(*A*), through (*B*) and (*C*), to pattern (*D*), indicating unity standing-wave ratio. Very frequently, this is all that a standing-wave indicator is required to do, as when adjusting tuning stubs, impedance transformers, plungers, line stretchers, crystal mounts, and so forth. In this operation, both hands are free to make the adjustments on the component. Similarly, production adjustment of components can be carried out rapidly in this manner, and individual checks of optimum standing-wave ratio are indicated quickly.

An interesting demonstration showing the effect of variations in detector terminating impedance can be performed with the setup shown in Figure 1 by observing the change in the standing-wave pattern as a simple resistive load across the crystal output is varied.

Impedance plotting is simplified when using the automatic standing-wave indicator, because of the ease with which the amount of shift in the standing-wave pattern can be found directly in the desired terms of wave length or angle.

If for some reason, the automatic standing-wave indicator cannot be used to advantage in obtaining the required information, such as when measuring very high standing-wave ratios, the probe may be operated manually in the ordinary way, and the amplifier meter used for indications.

Figure 5. Two simultaneous standing-wave patterns demonstrating effect of recurrent change in terminating impedance

Another novel feature of the automatic standing-wave indicator is its ability to indicate simultaneously multiple standing-wave patterns. For example, Figure 5 illustrates two simultaneous standing-wave patterns caused by recurrent changes in the terminating impedance. The particular pattern shown was generated by applying a small modulating square-wave voltage to the crystal detector terminating the transmission line shown in Figure 1.

The effects of certain types of transmission-line switching devices can be similarly observed. Still another application of the multiple-pattern scheme permits simultaneous observations of the standing-wave patterns arising at different generator frequencies, as the different frequencies are rapidly switched in succession. Separate klystrons may be used for this purpose.

The foregoing examples of the capabilities of the automatic standing-wave indicator serve also to illustrate its utility as an instrument for lecture or classroom use in making dramatic demonstrations of standing-wave phenomena.

Recent Research on Pulsed Light Sources

W. T. WHELAN
ASSOCIATE AIEE

Synopsis: The determination of the dynamic characteristics of arc discharges lasting for less than two microseconds, and recent developments in the application of hydrogen thyratrons to stroboscopic light sources are reported. It is pointed out that electrical circuit conditions prevalent in single flash or low repetition rate gaseous discharge lamp systems are considerably different from those existing in high repetition rate, multiple-flash circuits. Improvements in multiple-flash systems are described and their synchronization with high-speed cameras which use internal optical shutters is explained. Certain electrical features of a recent high-speed motion picture system utilizing synchronized flashlighting are reviewed. The need of further research and development on gaseous flashlamps is indicated.

RECENT technological developments have created increased interest in the art of high-speed photography. Single pictures of self-luminous phenomena in which exposures as short as 1/100 of a microsecond are realized with the use of a Kerr cell shutter. Classic spark shadowgrams with exposures of the order of $^1/_{10}$ microsecond are common in ballistic research. Single exposure, stroboscopic photography which has been made possible by the introduction of modern high-pressure gaseous discharge lamps and exhibits effective exposures ranging from 100 through several thousand microseconds is becoming commonplace. The desire to take motion pictures of short-lived events has led several manufacturers to introduce high-speed motion picture cameras capable of several thousand pictures per second with exposures varying from 50 to several hundred microseconds. Edgerton and his associates have introduced systems which combined fast motion picture cameras and gaseous discharge, stroboscopic light sources. The present paper recounts investigations carried out at the Naval Ordnance Laboratory at White Oak, Md., on this general problem of combining these flashlamp light sources with commercial high-speed cameras. The greatest part of the work was directed toward developing circuits which would permit operation of the flashlamps in synchronism with commercial cameras at higher voltage and consequently higher power input levels than those attempted previously.

Since action stopping by means of short exposure is the real justification of the complexity of synchronous pulse lighting it is obvious that extreme brevity of the light output is required. For ballistic research, exposures in excess of 1 or 2 microseconds are considered too long. In this respect the pulsed light sources discussed here differ from the longer duration single flash counterparts. The manner in which photographic negatives integrate total light to effect their exposure requires extremely large peak light output in order to produce useful photographs when the total luminous interval is made short. Because the light output is a function of the electrical input, this demands a relatively large peak power input during the flash. The level is of the order of 1 megawatt.

All of these pulsed light sources are excited by capacitor-fed discharges or modifications thereof. One of the notable variations is the transmission line-fed discharges in which the capacitor bank is replaced by a charged transmission line. The importance of such a system is that the electrical pulse shape and length is controllable by the proper choice of transmission line parameters.[1] Other circuit details remain unaltered. At the Naval Ordnance Laboratory, this latter method has been used with some success. A future report is planned.

Paper 48-236, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 20, 1948; made available for printing August 30, 1948.

W. T. WHELAN is with the Naval Ordnance Laboratory, Washington, D. C.

Electrical Characteristics of Flashlamp Loads

A study of the input power and load resistance variations during the discharge was the first undertaking in this series of investigations. The reason for this was that the available information on the pulse behavior of flashlamps was meager, contradictory, and specifically applied only to single-flash discharge circuits. The behavior of these single-flash circuits is considerably different from the practical multiple-flash circuit because of the much larger capacity of the energy storage capacitors used with the former circuits. For this reason, it was feared that what information was available was inapplicable. Larger capacity with the resultant higher discharge energy is permissible in nonrepetitive systems because lengthy rests occur between operations and the average energy input is kept small. As a result of the very large capacitor used, these single-flash circuits are always highly overdamped and the electrical discharge can be considered as simple R-3 transients, that is, wiring inductance is of little concern. In this way, apparent average values of the discharge resistance have been computed from the length of the discharge current pulse. For high-speed multiple flash service, however, two requirements demand the use of smaller storage capacitors: (1) because of the higher repetition rate, the input energy per flash must be reduced; otherwise, flashlamp destruction from excessive heating will occur; (2) a short duration flash of 2 microseconds or less is desired and a reduction of capacity will result in shorter discharge pulses. The reduction of storage capacitance can be better appreciated by considering the usual range of capacitance values used in single-flash service with the normal multiple-flash service; the former range commonly from 10 to 500 microfarads while the latter seldom exceed 0.1 microfarad and are sometimes as low as 0.01 microfarad.

Figure 1. Typical pulse modulator circuit

V1 = Hydrogen thyratron, type *5C22*
V2 = Flashlamp, types *FT-121, FT-125* or *FT-127*
V3 = Clamping diode. Pair of parallelled type *8020's.*
G = 20 kv protective gap

C2 = Pulse coupling capacitor
L1 = 2-henry charging choke
L2 = 1-millihenry closing choke
L3 = 100-microhenry noise suppression choke
E_B = 6–8 kv power supply

Actual determination of the lamp resistance during the short-lived discharged pulse was made by taking simultaneous oscillograms of the voltage across the arc and the current through it. The oscillographs used were of the fast-sweep, synchronoscope type and employed the new type high-intensity cathode-ray tubes. These tubes operate at 15 kv over-all accelerating potential and permit photographing of transients in which the spot velocity exceeds 50 inches per microsecond. A special 0.1-ohm current shunt was devised which had less than 0.001 microhenry effective series inductance. The suppression of the series inductance was necessary to reduce the shunt sensitivity to the rate of change of the surge current. No amplifiers were used because the current and voltage amplitudes were more than sufficient to deflect the oscillograph beam. Time variations of the apparent arc resistance were obtained by a point-by-point division of the arc voltage drop oscillogram by the arc current oscillogram. Investigation of the commercial flashlamps suitable for multiple-flash service showed that the dynamic load resistance of the conducting gas column, as determined from the oscillograms, fell extremely low during the impulsive discharge. Actual measurements indicated that values of this resistance at crest current ranged from 1 ohm to about 10 ohms, depending on tube type in use. The instantaneous power input was obtained by multiplying the two oscillograms. Measurement of the light output required the use of amplifiers; special video amplifiers with an 8-megacycle bandwidth were used. The light-to-electrical signal transducer used was the common 9-stage photomultiplier tube. Wideband response to match the amplifier was provided in its circuits.

The inevitable lumped wiring inductance encountered in practical setups, together with the small values of capacitance used in multiple-flash service resulted in discharge circuits which were nearly always underdamped. As a consequence, the wiring inductance is important in limiting crest current and the pulse width is determined by the wiring inductance and the storage capacity. Oscillatory discharge current would result if a bilateral switch were used in these circuits to connect the storage capacitor bank to the lamp load. This condition is an important factor in the selection of the switching device since an oscillatory discharge would make possible uncontrolled multiple flashes of the lamp and an accompanying lengthening of the flash duration.

Switch Problem

This single requirement that the switch must be a rectifier highlights the switching device problem upon which the ultimate success or failure of any high-speed multiple-flash system rests.

Peak currents ranging from 500 to 2,500 amperes were measured when operating at the high voltages used; thus a switch was required which exhibited extremely low series resistance and high current-carrying capacity. In addition, the switching device had to handle these surge currents at rates as high as 3,000 times per second under normal operating conditions. Normal crest voltages of 10 to 15 kv were switched and recovery rates as high as 50 volts per microsecond were observed. This meant that recovery time of the switch had to be extremely short.

As a starting point in the choice of a switch to meet the foregoing requirements, the usual switching methods which had been used successfully in other stroboscopic light systems were tried for adaptability. Rotary gap switching which proved popular in early radar proved too noisy, unpredictable, and incapable of ready synchronization. Triggered stationary gaps were useful also but suffered from time "jitter," burning, and excessive noise. The use of small, glass-enclosed ignitrons, while good at low repetition rates, failed from overload at high speeds. Inconvenience of their necessary vertical mounting and sensitivity to mechanical shock made them unsuitable for portable gear. The hydrogen thyratron impulse switch, which was developed to replace the rotary gaps in war-time radar, at first appeared as an unlikely possibility. This was because the peak current ratings of the two largest types were only 90 and 325 amperes. However, because of the simplicity of synchronization, the larger of the two types, the *5C22*, was tried. After considerable experimentation, it was found that this tube could be made to commutate 2,500 ampere surges at 3,000 cycles per second with no apparent damage. These results were certainly unexpected from a consideration of the tube ratings. Cathode sparking was noticed, but useful tube life was realized with little evidence of cathode disintegration. Spurred by this success, the small type *4C35*, which possessed a 90-ampere

Figure 2. The pulse modulator unit

Figure 3. Flashlamps which have been used successfully with the modulator

peak rating, was tried. Again successful switching was realized.

Camera Synchronization

At this point the question often raised is why should one ever use cameras with internal shutters when the flash duration, itself, can be used to provide shutter action? The answer is not immediately apparent and a digression must be made here for the answer to this objection. It should be realized that the high-speed type camera utilizes continuously moving film which normally is accelerating throughout the motion picture, and may reach a speed of 100 feet per second. As a result, the most important motion which must be "stopped" is that occurring between the small image formed by the lens system and the moving film itself rather than that of the moving objects in the field. A small fraction of a millimeter relative motion between image and film may represent an equivalent apparent motion of many inches of the photographed objects, including even the immobile objects. An exposure as short as one microsecond results in sufficient blurring from image motion to degrade picture quality. In those cameras using internal optical shutters, this unwanted effect is practically eliminated by the shutter system which consists usually of a rotary compensating prism which moves the optical image in such a manner that relative motion between film and image is eliminated. Such a system, together with microsecond exposures of the actual moving event being photographed, makes possible exceedingly high definition photography. For optimum compensation and proper frame width in such a system, it is essential that the light pulse occur at the instant when the internal shutter is at the "wide open" position. Continuously accelerating film also requires a corresponding shift of flash rate, if properly spaced pictures are to be realized.

Each of the commercial cameras which had internal shutters presented a different synchronization problem. The best solution consisted of small synchronizing alternators mounted on the shaft of the main camera driving motor. This procedure was adopted in order that the delicate mechanical features of the camera mechanism might be disturbed as little as possible. Operating on the variable reluctance principle, the auxiliary synchronizing alternator consisted of alternate ferrous and nonferrous slugs which passed between the poles of a small Alnico V magnet. The magnet was wound with a pickup coil in which a signal was induced as a result of the flux pulsations. It was a simple matter to choose the number of slugs so that the coil signal frequency corresponded to the shutter frequency. Proper phase relationship between synchronizing signal and the shutter was accomplished by actually changing the angular position of the magnet with reference to the shaft. This synchronizing signal was then available for use with whatever type switch might be selected.

Performance Tests

No serious attempt was made to discover the top switching rate because an upper limit of 4,000 frames per second exists, set by the available commercial 16 millimeter cameras, but success was experienced at 5,000 cycles per second although the operating voltage had to be reduced to prevent premature flashlamp destruction.

In attempting to explain the wholly unexpected success of the thyratrons when loaded so far beyond their ratings, it must be pointed out that the duration of the discharge in these circuits is always one microsecond or less and that the usual picture-taking interval is less than three seconds in length. Such short bursts of service, while adequate for motion pictures, do not add up to an impressive tube life figure when stated in hours, but in terms of pictures taken, a truly "long" life is had. A typical tube was used in over 200 motion pictures which were taken on 100-foot reels of 16-millimeter film. During this time, it operated at an average rate of 2,500 flashes per second for two seconds per reel. At the end of this time, the tube, apparently still good, was replaced as a matter of routine. Unfortunately, no rules can be set regarding tube life under such strenuous conditions of service, but it is felt that the example cited is representative of what can be expected. Thyratrons from several different manufacturers have been used with no interchangeability problems. In any case, the tubes have repeatedly outlived the quartz lamp units in service.

The usual pulse unit in use at the Naval Ordnance Laboratory uses the *5C22* thyratron instead of the smaller *4C35*. This choice was made because of an annoying grid "spike" voltage which appeared when operation above 10 kv was attempted. This spike apparently is the result of the initial breakdown occurring between plate and grid, rather than plate and cathode and seems to be intensified by cathode sparking. This grid spike caused heater-cathode punctures in the cathode follower driver which fed synchronizing signal to the thyratron grid.

The use of the hydrogen thyratron prevented underdamped discharge circuits from oscillating as hoped. This effect, desirable as it was, made it necessary to limit the self-inductance to as low a value as possible; otherwise, excessive underdamping caused the energy absorbed in the arc during the single half-oscillation permitted by the thyratron to fall to low values, and this of course resulted in a decided falling off of light output. Practically, this means that the effective lumped series inductance had to be limited to less than five microhenries when the available lamps and the usual range of storage capacitors were used. It should be noted that this adjustment of circuit damping is best carried out by control of the effective series inductance because neither the operating capacity nor lamp

Figure 4. Hydrogen thyratron switch tubes 5C22 (left) 4C35 (right)

resistance admit large modifications in these circuits.

In the circuit used, a slight underdamping was found actually desirable because it resulted in a reversal of the instantaneous thyratron plate-to-cathode voltage immediately after discharge, and this negative "overshoot" was helpful in aiding rapid deionization of the switch tube.

Circuit Discussion

A brief review of one of the several possible pulse circuits follows: As shown in Figure 1, this pulse modulator circuit resembles closely certain high-level radar modulators. Since the basic circuit can be found in any radar textbook,[3] only a brief résumé of its operation is made here. V1 is the hydrogen thyratron switch tube and V2 is the gaseous light source. L1, L2 and V3 constitute the charge-up circuit and C1 is the energy storage network. The direct power supply, E_B, is connected to the positive and negative terminals. The purpose of the diode, V3, is to permit operation of the light source at a cyclic rate lower than that set self-oscillation frequency of L1 and C1.[3] C2, R1 and L4 form a coupling network which delivers the synchronizing signal to the thyratron grid. L3 is a grid suppression choke coil which prevents hash from being fed back into the driver stage. G is merely a protective gap which prevents overvoltaging C1 in the event that modulator load, V2 is inadvertently disconnected.

A typical cycle of operation may be reviewed. Prior to arrival of the synchronizing pulse, C1 has been charged to approximately $2E_B$ and prevented from discharging to the power supply voltage, E_B, by the "clamping" diode, V3. At the proper instand a steep-fronted, positive, trigger pulse of 150 volts amplitude is applied to the grid of V1 which causes this thyratron to break down. Firing of V1 connects C1 across the flashlamp, V2, and since the voltage to which C1 is charged is more than sufficient to force the breakdown of the lamp, V2, C1 discharges through with the resulting light output. Very little energy passes through L2 which parallels the lamp because of its high impedance to the pulse voltage. L2 must be capable of withstanding the full pulse voltage across its terminal, however. On the next recharge cycle, C1 is brought to a final voltage of nearly $2E_B$ by the charging choke, L1, and the system again awaits the synchronizing pulse.

It will be noticed that an inductive charging circuit is used instead of the more usual charging resistor of low repetition rate systems. In multiple flash systems, this complication is necessary because the large amount of power required by each lamp results in too great a power loss in the low efficiency (50 per cent maximum possible) resistance charging system. A single lamp operated 2,000 times per second with a storage capacitor of 0.05 microfarad, charged to a peak voltage of 15 kv, represents an average power dissipation of 2.25. Using resistance charging, a minimum power requirement of 4.5 kw would be imposed, while an inductive charging system would demand only the load power plus small circuit losses. The inductive charging circuit and clamping diode operates also at various repetition rates with no adjustments required, while the resistive charging networks cannot be so operated. This type of variable frequency operation is desirable because the camera speed is adjusted readily to any value less than its rated maximum and is frequently so operated for special purposes. The only drawback to this method of charging is the difficulty of obtaining commercially a reactor which has sufficient current rating and the requisite insulation across the winding as well as from winding to ground, and the need of the high-current high-vacuum diode which possess an inverse voltage rating of 10 kv, or more.

System Features

The modulator outlined in Figure 1 has been used also for multiple-spark operations. Repetition rates of 2,000 cycles per second were obtained successfully with no marked decrease in thyratron life, even though, because of the extremely low resistance of the spark gap, a larger amount of energy was dissipated in the thyratron than when used with flashlamps. Light sources consisting of short gap sparks are useful in certain types of ballistic photography because they can be readily converted into intense point-sources of light. No known previous attempts have been made to operate a spark at high repetition rates for photography purposes in this manner. The multiple spark source awaits development of suitable photographic techniques before its unique features can be exploited as research tools.

In addition to the flash synchronizing circuits and high level pulse forming circuits just described, a practical picture taking system requires a considerable amount of auxiliary cycling and interlacing equipment. Most photography problems require the use of several lamps to provide lighting free of unwanted shadows. In the simplest problems the several lamps may operate simultaneously, but in the majority of cases, where large fields are to be covered, progressive sequence lighting which "follow" the action across the field is desirable. The control equipment developed at the Naval Ordnance Laboratory allows the operator to preset any sequence of lighting which experience dictates will be necessary. Control of the individual light sources is exerted conveniently by means of grid block switching of individual buffer amplifiers which deliver the synchronizing trigger signals to the thyratrons. Through self-contained dividers, the operator can select any lamp or group of lamps for operation at subsynchronous rates. Such lighting offers varying degrees of contrast on successive frames; this feature is sometimes highly desirable in motion pictures taken for frame-by-frame analysis of a phenomenon.

Power supply considerations are a relatively important item in any multiple lamp pulsed light source system. As has been mentioned, the average power which must be delivered by the direct power supply exceeds several kilowatts per lamp when the picture is being taken. However since the duty cycle of the power supply is so small, it is obviously not necessary to provide the full continuous duty capacity for these short term demands. It is important, nevertheless, that the regulation of the power source be small, otherwise unwanted interaction of individual lamps will occur. Transformer-rectifier sets were chosen instead of rotary machinery because of the high d-c voltage (7,000 volts) used. A full wave, 3-phase bridge rectifier circuit was chosen because of its many desirable features.[4] Single phase rectifier operation to multilamp installation is not advisable. Individual power supplies were built as units capable of delivering 15 kw each because of the greater handling convenience and availability of its component parts. For load demands in excess of this power, additional power units were used. A great advantage of this type of power supply is that failure of a single rectifier bank does not render the lighting system completely inoperative. No d-c filters were used on the power supplies because the low level of the output ripple from the 3-phase bridge connection was not objectionable.[5]

Radio-frequency interference propagated over the power lines proved troublesome. This was reduced by appropriate filters and the use of the polyphase power supply. Radiated inter-

Figure 5. A series of enlarged frames from typical motion picture of a 1-inch steel sphere entering water. Silhouette lighting was used and camera speed was 2,500 pictures per second

ference from the actual discharge circuit was suppressed by the use of coaxial cable to connect lamp and modulator. Ordinary *RG8*/U-type cable was used with success if the length was kept less than 20 feet. Longer sections of line occasionally gave trouble because of reflections which arose from improper termination. Excessive attenuation did not appear to be a problem. The polyethylene insulation of these cables is sufficient to resist 25-kv surges caused by mismatch terminations.

As a result of the present series of investigations, it is clear that further development of the quartz discharge lamp is required. The presently available lamp types are excessively fragile and are subject to frequent breakage from improper handling. The input per flash at the higher repetition rates should be greater in order that the number of lamps required for a specific "take" might be reduced, but this is impossible with existing lamps. The gas physics of these lamps seems to be satisfactory, since the duration of the deionization tails was not found to be excessive. While the present thyratrons are usable as switch tubes, it is desirable to have larger ones available possessing cathode emissions that will permit operation within ratings.

The investigation was sponsored by the office of Naval Research.

Summary

A system employing pulsed gaseous light sources designed to operate in synchronism with high-speed motion picture cameras has been developed. A distinct improvement over previous systems with regard to definition and flexibility has been realized. This type of operation is made possible by precise synchronization of the internal camera shutter and the firing of the flashlamp. The operating voltage of the lamps is of the order of 10 to 15 kv, which is considerably higher than previous flashlamp systems used. As a result of the higher operating voltage, lower capacity energy storage capacitors are possible and light pulses, whose durations are as low as one microsecond, result.

As many as 3,000 to 4,000 pictures per second can be taken with presently available cameras and flashlamps; no lower frequency limit exists. Unexpected success has been realized with hydrogen thyratrons serving as switches to connect the lamp load to the storage capacitor at the proper instant. Discharge currents as great as 2,500 amperes have been recorded.

The system has been designed so that a number of commercial flashlamps can be used interchangeably without circuit alterations. In addition, multiple-flash spark gaps have been successfully substituted for the flashlamp. Operational convenience and flexibility have been incorporated into the system by way of compact, portable, high-voltage lamp units and elaborate interlacing and sequence circuits for light control. Power supplies are designed for operation from standard 208-volt 3-phase lines. A need for thyratrons of larger current capacity, and flashlamps which are mechanically and electrically more rugged is apparent from this investigation

No Discussion

The Magnetic Fluid Clutch

JACOB RABINOW
NONMEMBER AIEE

AN apparently new type of magnetic fluid and several classes of new devices utilizing this fluid have been developed at the National Bureau of Standards. Among them are new types of hydraulic actuators, dashpots, and clutches. These developments have stemmed from an extensive research program on electronic digital computers for the office of the chief of ordnance, Department of the Army. Such machines require electromechanical input and output mechanisms which employ, among other elements, magnetic recording tapes and their associated transfer devices. In some of the applications, extremely rapid accelerations are necessary, with frequent starts, stops, and reverses. Since it is desired that velocities of the order of 20 feet per second be reached in a few milliseconds, a search was made throughout the field of fast-acting motors, clutches, and brakes in order to find equipment suitable for this duty. One of the items found was the clutch of W. M. Winslow, which uses electrostatic attraction between finely divided insulating particles suspended in oil and two conducting clutch plates.

The electrostatic clutch suggested the possibility of devising a new type of magnetic clutch, using two magnetic plates and substituting a suspension of magnetic particles for the electrostatic mixture. A new material and several new devices have resulted from these experiments. The most obvious application of the principle has been in electromagnetic clutches, but the electromagnetically controllable mixture appears to offer considerable promise for other uses as well. When used as a filler in a dashpot, the suspension of iron in a suitable liquid offers great advantages in that, by the employment of suitable electromagnetic control, the characteristics of the dashpot can be made to be a function of position, velocity, acceleration, or any combination of these factors.

Simple electromagnetic valves, with no moving parts, similarly can be employed to control the flow of this mixture through hydraulic systems, thus presenting a new area of experimentation in the field of servo-mechanisms.

Principle of the Clutch

The magnetic fluid clutch operates on the basic principle that when the space between two parallel magnetic surfaces is filled with finely divided magnetic particles and a magnetic field is established between the two plates, the magnetic particles bind the plates together against movement parallel to their surfaces. The magnetic particles may be finely divided iron which, for most applications, is mixed with a liquid such as oil, to prevent packing and to afford smoother operation of the clutch. When a portion of this mixture is acted on by a magnetic field, the iron particles are mutually attracted, bind together in the field, and the mixture seemingly "solidifies"—an effect readily demonstrated by lowering a small permanent magnet into a beaker of the iron-oil mixture (Figure 1). As the magnetic field can be produced by an electric current, a very simple means is thus obtained for the control of the binding force over a very wide range.

Advantages of the Magnetic Fluid Clutch

Preliminary results at the National Bureau of Standards indicate that the electromagnetic fluid clutch has numerous advantages over many other existing types. It is characterized by extreme smoothness of action because all contacting surfaces, both of the plates and of the iron powder, are coated by a lubricant. The clutch is easy to control and requires very small amounts of electrical power. The control is extremely smooth from the minimum, which is determined by the viscous drag of the oil, to the maximum, which is controlled by the magnetic saturation of the iron. Unlike other electromagnetic clutches, which follow a square law wherein the torque is proportional to the square of the current, the torque in the new clutch exhibits the square effect to a markedly less degree, and, in some clutches, the torque-versus-current curve is almost a straight line below saturation.

Another unusual and desirable feature found in these clutches, particularly when used at low flux densities, is that the value of static friction does not differ measurably from kinetic friction; hence, no discontinuities in torque exist at the instant of initiation of slip. This feature contributes greatly to the smoothness of the clutch action, since chattering in an ordinary dry friction clutch is mainly due to the difference between the static and kinetic friction.

Because it has no axially moving parts, the clutch is very easy to build, consisting essentially of a driving and a driven member which do not change relative position, except in rotation. As slipping occurs only between the extremely fine iron particles and between the iron particles and smooth face surfaces of the clutch, and as all the surfaces are lubricated, wear appears to be negligible. Moreover, if any of the surfaces are worn off, the iron dust thus generated simply adds to the iron powder already in the oil mixture. The gaps, as normally employed, are fairly large; therefore, any such wear will have minor effect. In the clutches tested at the Bureau, no wear has been noted, but because extensive life tests have not yet been run, it is not possible to rule out wear completely.

Paper 48-238, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 20, 1948; made available for printing September 3, 1948.

Design Factors

Before describing the several forms of magnetic clutches built and tested at the Bureau, it may be well to generalize somewhat on the design of such couplings. Figure 5 shows the general arrangement of an electromagnetic clutch where both the driven and the driving members are represented as a single magnetic unit. Figures 6, 7, and 8 show three alternate methods of dividing the magnetic structure into two parts for the transmission of power. It will be recognized that Figure 6 is the configuration most generally employed in dry magnetic couplings, while Figures 7 and 8 show alternate arrangements particularly suitable for the use of magnetic powder and oil instead of dry friction. Figures 9 and 10 are other arrangements where the magnetic structure is cut at more than two places so that parallel plate operations may be obtained in order to increase the area of action. While all figures show a single circular coil, it is quite obvious that separate coils, spaced like the poles of an electrodynamic machine, may be employed. The single coil is favored because of its simplicity of construction and excellent magnetic efficiency. Many other forms of magnetic circuits can be employed, depending on the materials used, results desired, cost, and other factors.

The design principles of the magnetic circuit of the clutch are no different from those used in all other electromagnetic machinery, with the possible exception that the value of the permeability of a suitable mixture of the carbonyl iron and oil is approximately eight times that of air. A permeability of eight implies that an iron-powder gap of, say, 0.080 inch has the same reluctance as an air gap of 0.010 inch. This increased permeability of the gap greatly simplifies the design and construction of practical electromagnetic couplings of the type described. The permeability was measured by means of toroidal coils wound around Lucite rings containing a known quantity of the magnetic mixture (Figure 2). Higher permeabilities can be obtained by using less oil, larger particles, or aggregates of large and small particles, but it is doubtful that very much better values than those reported can be obtained with carbonyl "E" powder mixtures.

Figure 2. Toroidal coils are wound around these Lucite rings

One of the main considerations in the choice of gap dimensions is the effect of viscous drag. For example, in a clutch of the type suitable for automotive use, the viscous drag of the clutch plates when the magnet is de-energized must be kept to a minimum, while in an overload clutch this effect may be of no importance.

The magnetic clutches thus far built at the National Bureau of Standards are of a basic and simple form, that is, with the spacing of the plates fixed, though this construction has the disadvantage of producing appreciable viscous drag at high speeds when the clutch is de-energized. For one of the bureau's experimental clutches (Figures 11 and 19), the drag is approximately 1.0 pound-inch at 1,000 rpm and varies linearly with speed. This drag may be minimized in several ways, such as using a thinner mixture of iron and oil, using lighter oil, increasing the spacing between the plates, and, of course, driving the clutch at lower speeds. Mechanical devices which change the spacing of the plates automatically when the clutch is demagnetized can be employed, and the number of other expedients is unlimited. Normally this viscous drag is a small fraction of the clutch torque, and the heat generated can be readily dissipated. In regard to automobile applications, the low idling speed of gasoline engines is advantageous.

In considering the design of magnetic circuits, it is concluded that the use of gaps in parallel, or single gaps of large area, entails large amount of iron and small copper losses, while the use of gaps in series reduces the amount of iron but requires more excitation to overcome the total resultant gap length. Which method of attack is preferable depends

Figure 4. The holding ability of the magnetized iron-oil mixture used in the new type of electromagnetic clutch is demonstrated in this experiment at the NBS. A 2-inch-square plate immersed in magnetic fluid energized by an electromagnet supports the weight of the girl (117 pounds)

Figure 3. Laboratory test apparatus devised at the NBS to determine the shearing force that magnetic fluid used in the new type clutch will resist. The 2-inch-square iron plate (in hand) will sustain a pull of 200 pounds without moving when 10 watts of electric power are supplied to the coil

Figures 5–10. Cross-sectional drawings of several magnetic clutches

upon such factors as the availability of electric power, considerations of weight, and size. Multiple-plate clutches can be designed so that the sets of plates are either in series or in parallel. The 3-plate clutch of the design shown in Figure 21 (wooden mock-up) can be expanded readily to have any desired number of alternate driver and driven plates, as shown in Figure 25. This clutch, which uses the series gap arrangements, is very compact, but heat dissipation presents special problems, particularly if the clutch is to be used continuously in constantly slipping condition. Air or liquid cooling can be provided in any known manner.

Where low inertia is required in the driven member, as in high-speed servo work, it is desirable to make the exciting coil and magnetic iron a part of the driving member in so far as possible. Only a very thin member is then needed to pick up the torque in clutches such as shown in Figures 10 and 26. The thin driven plate, which normally is made of iron or other magnetic material so as not to introduce any unnecessary reluctance into the gap, may be made of various nonmagnetic materials as well. It was found that plates made of such materials, when introduced into the magnetic gaps, experienced torque because of the attraction of iron particles from opposite sides of the plates. Work on this effect is still in process, but it has already been found that mesh, or plates with perforations experience torques comparable to those obtained with iron plates. This effect is particularly important because, when thin iron plate is used, there is always the possibility that mechanical eccentricities may be greatly exaggerated by the magnetic pull and the plate deformed sufficiently to contact one or the other of the magnetic surfaces. This type of unbalance of the magnetic pulls is well known to the designers of rotating electrical machinery, and similar difficulties with bearing play and shaft flexibility may be experienced in the magnetic fluid clutches. The thin lip shown at the edge of the driven member of the clutch in Figure 26 was built to stiffen the cylinder. By using nonmagnetic materials this difficulty is obviated.

Another problem which arises in connection with these clutches is that of sealing the oil-iron mixture in its compartment. There are two separate places where such sealing generally is required. One is the point where the shaft supporting the internal member leaves the assembly, and the second, if an internal coil is used, is the point at which the leads are brought out. Good results have been obtained by using rubber "O" rings at the shaft bearing, but there is no doubt that other types of packing can be employed successfully. If there is danger of the iron particles getting into ball bearings, it may be desirable to add a magnetic lock beyond the oil seal to trap any particles of iron which get through the seal. The oil that passes beyond this point would then be clean and should have no harmful effect on the bearings. Such a magnetic lock may consist of a permanent magnet ring flanked by two iron washers, as shown in Figure 17.

Two other methods being tested for sealing the mixture into the clutch consist of using labyrinth seals, particularly when the clutch is to be used only in a horizontal position, and the use of spiral grooves on the shaft or on the bearing, arranged so that any mixture reaching the seal is automatically pumped back into the internal cavity of the clutch.

Generally speaking, it appears advisable to place the electrical winding inside the clutch for several reasons: this placement reduces the amount of wire needed; it puts the torque surfaces at the maximum radius; it permits better dissipation of heat generated by the friction surfaces; and it reduces the over-all size and inertia of the clutch. However, there may be times when these considerations are not important, as when seals present difficulties, particularly in the case of very thin shafts. The coils may then be placed on the outside of the friction surfaces. Such a design is shown in Figure 20.

It is possible also to make the energizing coil completely separate from the clutch so that the coil is not revolved but transmits the magnetomotive force to

Figure 11. First NBS test model of practical clutch. Current supplied through the two slip rings energizes a coil in the disk-shaped central chamber, and hence through the magnetic fluid in the intervening space

Figure 12. Disassembled view of the central chamber of the first NBS test clutch, showing the magnet coil on the upper plate surrounding the free center disk which connects to the driving shaft

Figure 13. A close-up of a filling hole in the upper driven plate of the first practical model of the NBS magnetic fluid clutch. On the left the driving plate turns freely in the demagnetized mixture of powdered iron and oil between the upper and lower driven plates. When the clutch is energized, right, the magnetic flux acts on the iron powder suspended in the oil, and the mixture forms a virtually solid mass

the working faces through short air gaps. This can be accomplished at some loss of electrical efficiency and appears suitable only for very small sizes, where the power demands are low and the simplification is justified.

When an electromagnetic fluid clutch is used as a brake, slip rings are not necessary. Another very promising approach to the problem of their elimination is to employ a built-in a-c generator which may consist of no more than a coil mounted on one of the clutch members and arranged to pass through the field of a

Figure 15. The practicability of the magnetic fluid clutch was first demonstrated by immersing a small motor frame and field windings in a bath of powdered iron and oil. Application of current to the field windings causes the cylindrical iron rotor (substituted for the usual armature) to lock firmly

permanent magnet, or an electromagnet, mounted on the stationary frame of the machine. The alternating current thus produced may be applied directly to the clutch windings, or may be rectified before being applied. If nonlinear resistive elements are added to the circuit, interesting possibilities in controlling the clutch torque by means of speed variations are presented. If the field structure is mounted on the other rotating member of the clutch, the voltage developed will be a function of the difference in the speed of the two clutch members. While complete lock-in could not then be obtained, characteristics very similar to fluid couplings would be achieved.

Experimental Results

The first experiments performed at the Bureau consisted of taking the field structure of an ordinary small 2-pole motor, replacing the armature with a cylindrical iron rotor, and dropping the whole assembly into a beaker containing the iron-oil mixture. Voltage was then applied to the field winding and the locking torque on the rotor was examined. The torque was so great in this test that it was decided that the bearings must have "frozen" or that the rotor shaft had bent out of shape, although subsequent tests showed this not to be the case. A design as shown in Figures 11, 12, and 19 was constructed to check for the presence or absence of magnetic shear effect. This model was used for much of the experimental work at the Bureau. The bearings are external to the oil mixture, and, by using a vertical shaft, oil seals and their attendant friction are eliminated. The results indicated that the first experiments with the motor frame were quite valid in that large torques were no doubt due to the small gap present

This motor as later remodeled (Figures 15, 16, and 18) was used with several sizes of rotors to determine the effect of gap length on the resulting torque. This particular type of assembly, using the conventional motor frame with laminated magnetic circuits, is especially suitable

for magnetic clutches to be operated on alternating current. Using a mixture consisting of nine parts of carbonyl E iron and one part of oil by weight, the following torques were obtained: 2.5 pound-inches with a 0.062-inch gap; 3.0 pound-inches with a 0.025-inch gap; and 3.5 pound-inches with a 0.012-inch gap. These torques were obtained at low speed, and the effects of speed and of gap length are shown in Figure 27. In order to minimize the residual magnetic effects, the cylindrical rotors were made of 47 per cent nickel steel. This construction is suitable for d-c operation, while a laminated disk construction would be more suitable for a-c use. When alternating currents are used to energize the model, the torques are somewhat lower (Figure 28).

Figure 20. Design of a clutch with the electrical winding on the outside of the friction surfaces

Various experiments were performed with the flat-plate clutch (Figures 11, 12, and 19), the magnetic components of which are made of 47 per cent nickel steel. The inner driving plate is a disk 0.062 inch thick by 3 inches in diameter and the iron-oil gap on each side of the disk is 0.062 inch. The coil consists of approximately 200 turns of number 28 wire with a d-c resistance of 15 ohms. In the design of this clutch, no effort was made to make an efficient magnetic circuit, since the gap area is large relative to the cross section of the magnetic material surrounding each side of the coil.

Tests on this clutch indicate that the static friction is not appreciably different from the friction obtained under conditions of slip. This can be seen from a typical set of curves shown in Figure 29. The relationship between exciting current and torque is shown in Figure 30. The magnetization curves, it will be noted, are practically linear through zero. The clutch does not appear to obey the square law as is generally expected in magnetic devices. The reasons for this are not clearly understood. In one experiment with the flat-plate clutch (Figure 14), the torque was measured on a spring scale attached to a point on the periphery of the driven plates by means of a thin cable. It was found that when the clutch was driven by the electric motor the pointer on the scale remained completely steady, in-

Figure 21. Cutaway model of a simple multiple-disk-type clutch. The electromagnet for energizing the magnetic fluid which normally fills the clutch casing utilizes the coil windings in the center of the clutch

dicating that the value of the torque did not drop with the increase in speed, an effect quite common in dry friction clutches and one which results usually in considerable instability under similar conditions of test. As may be expected, the clutch heated up appreciably during each run because of the energy dissipated in friction; this resulted in a lowering of the viscosity of the oil and a slight change in torque.

Determination of the type of liquid to use as a vehicle is based on such factors as difficulty in sealing, ability to withstand high and low temperatures, chemical stability, availability, and price.

Typical results of tests on different types of iron and various proportions of iron and oil in the mixture are shown in Table I. The behavior of the iron-oil mixture when magnetized and demagnetized may be visually examined through one of the filling holes of the flat-plate clutch. The liquid when unmagnetized looks like a heavy gray oil, as shown in Figure 13 (left), but when magnetized and subjected to shearing by revolving the inner plate, the material assumes a striated appearance as seen in Figure 13 (right). When the plate is moved

The parts are: (top) outer shell; (left to right) driving shaft, attached to end plate, with leads connected to the slip rings shown; inner member, attached to driven shaft; bearing and end-plate through which driven shaft extends

it appears that most of the shearing action occurs at the surface of the plate, with a great deal of rearrangement of particles. It has been suggested that different types of surfaces on the clutch plates may have interesting effects on the behavior of such clutches. Tests of these effects have not yet been made.

It has been found that in this particular clutch, a mixture of oil and carbonyl "E" iron, which is composed of particles with an average size of eight microns, gave the best results. This may not be true of other clutches or other conditions of tests. When dry powder is used in the clutch, the torques are of the same order of magnitude as when mixed with oil but eccentricity or misalignment of plates results in erratic operation.

Since the speed of response is of paramount importance in servo-mechanisms, the time of build-up and decay of torque was measured. This was done by means of a wire strain gauge attached to the rim of the driven member. The input voltage was applied to one pen of a multichannel recorder while the strain gauge was made a part of a 60-cycle bridge, the output of which was applied to a second pen of the recorder. The resulting record is shown in Figure 32. It will be noted that the torque rose and decayed in approximately 1/30 of a second. In some previous tests with similar equipment, torque-rise and torque-fall times of the order of 1/60 of a second were obtained.

Following these experiments, two small clutches (Figure 20) suitable for servo work were built into a model auto bus (Figure 22). In order to keep the construction simple, the coil was placed on the outside of the clutch proper. This construction required only one seal, achieved by using a small rubber "O" ring. The slip rings consist of copper wire wound in shallow grooves in a Bakelite drum. The wires were soldered together and turned in a lathe to approximately half their original thickness. This is also the type of construction used in the slip rings of the clutch shown in Figure 26. The coils, wound of number 42 enamel wire, have a resistance of approximately 12,000 ohms each. The magnetic circuit is made of 47 per cent nickel steel as in the two previous cases, with gaps of 0.032 inch. It was found that a current of eight milliamperes results in a torque of two pound-inches. This is the value at the knee of the saturation curve, with a value of three pound-inches obtained with

Figure 32. Time response for disk clutch

approximately 24 milliamperes. One of the clutches is locked to the frame and is used as a brake.

By controlling the current through the clutch and brake, acceleration and deceleration can be controlled easily, and the car can be made to run smoothly at low speed. The brake action is also very smooth and positive.

In order to study the effects of various surfaces, gap parameters, and other variables, it was decided to build a unit where such changes could readily be accomplished (Figure 3). It was constructed with a removable chamber in which various plates can be tested easily. The magnetic circuit is made of unannealed cold-rolled steel, resulting in large values of residual magnetism. This is overcome by means of a reversing switch provided in the electrical circuit. Using chambers with an internal width of 3/16 inch, it was found that when a 1/16-inch steel plate was inserted and the rest of the space filled with carbonyl "E" iron-oil mixture, the magnetic circuit reached the knee of its saturation curve with approximately 60 volts applied. The central plate (Figure 3) is kept centered in the chamber by four brass pins. It was found that the shear force on smooth plates, 1/16 inch thick, gave a maximum value of 20 pounds per square inch of surface. The rectangular plate gave values greater than those obtained later on circular plates due to the edge compression effects which it caused. When the magnet is energized, the iron-oil mixture becomes practically solid and can be held in any position without spilling.

Basing the design on the results obtained with this fixture, a much larger clutch was built in the bureau shops. This clutch is shown in cross section in Figure 26, and assembled and disassembled in Figures 23 and 24. The magnetic circuit again is of unannealed cold-rolled steel with the end plates made of dural. The coil has 600 turns of number 18 wire. Its total resistance is 3.5 ohms.

Figure 33. Low-inertia magnetic fluid clutch

In order to keep inertia of the driven member low, most of the magnetic circuit iron and the coil were made part of the driving structure. The driven member consists of a 1/16-inch-thick cylinder mounted on a brass disk which in turn is fastened to the driven shaft. Rubber "O" rings are used as seals as indicated in the cross section drawing. In the only test made so far, the clutch was mounted in a vise and the output shaft was turned by the use of a 3-foot lever. It was found that in this particular design, the static friction at high torques was not equal to the torque when the clutch was slipping, the first time this was found to be the case for such clutches. The reasons for the difference have not yet been ascertained. The change of torque amounted to approximately 25 per cent. However, the slipping torque, as observed on a spring scale driving the torque arm, appears to be very smooth. The relationship between torque and the magnetizing current is shown in Figure 31. Again no square-law effect is apparent. Additional tests on this clutch are under way.

In order to achieve higher torque-to-inertia ratios than in any of the clutches described previously, the clutch, shown in Figures 33, 34, and 35 was designed. Two symmetrical magnetic structures, slotted to minimize eddy current effects, are employed on both sides of a thin magnetic disk. The current-torque curve for this clutch is shown in Figure 36. Tests were made on the speed of response of this clutch when connected in the plate circuit of a vacuum tube. It was found that the clutch came up to a full speed of 1,270 rpm about 10 milliseconds after the grid of the vacuum tube was suitably energized.

Applications of the Clutch

The results obtained by the National Bureau of Standards in the experiments on the several forms of the magnetic fluid clutch suggest many possible uses for the new electromagnetic device. The automotive application mentioned previously is, of course, the most obvious one. Unlike fluid couplings of the type now common in automobiles, the clutch is not a speed-sensitive device. If the load is below the slipping torque of the clutch, no slippage occurs and the mechanical efficiency of the clutch is 100 per cent. The feature which particularly adapts the new clutch to automobile use is its easy controllability, which makes it especially attractive for use in automatic transmissions where permanently engaged gear trains are clutched in and out, depending upon the speed ratio required. Since the amounts of electrical power required to control the magnetic clutch are small, it is a simple matter to interlock the electrical circuits with the speed, throttle setting and power demands.

The field where these new clutches are expected to find their main application, however, is in servomechanisms. Here, friction clutches have been used, but their lack of smoothness, the changes in characteristics caused by wear, their nonlinearity, and the poor reproducibility of results have given rise to great difficulties. The new clutch should go far toward solving such problems. While servomechanisms can be operated by variable speed motors, hydraulic transmissions, and many other means, clutches and brakes have the very great advantage of low inertia-to-torque ratios. Electromagnetic clutches are particularly adaptable to serve as the final elements of electromechanical amplifiers.

It was found by experiment that the nature of the oil used in the magnetic fluid clutch has relatively little bearing on performance; hence, silicone liquids may be employed with excellent results, enabling the clutch to operate at very low and very high temperatures, an important consideration in military applications.

Another broad field of applications is in constant-torque and overload devices where the clutch is never de-energized. Permanent magnet clutches are particularly useful for such service.

Starter-Generator Control System for a Multijet Airplane

VICTOR B. HART
ASSOCIATE AIEE

THE starter and generator components used on a recently developed 6-engine jet airplane are in many respects identical to those that would be used on a reciprocating-engine-type airplane. One main difference, however, is the starter-generator itself. On a standard reciprocating-engine-type airplane, there are generally two units used, a starter and a generator. On this multijet-engine airplane, the starting and generating functions are performed by a single unit which is used both as a starter and as a generator. It is called a starter-generator, is rated at 400 amperes, 30 volts direct current, and is capable of supplying a continuous output of 400 amperes at engine speeds from 4,000–8,000 rpm. The electric system designed to control the starter-generator and its supporting components was patterned in the early design after comparable systems used on standard airplanes. Modification, and in some cases, complete redesign of parts of the control system were necessary in order to provide a system which would perform according to the more exacting requirements demanded of it.

Automatic Starter Control Disconnect

The first item that required consideration was the starting sequence. On standard airplanes, the starter generally becomes disengaged immediately after the engine has fired; however, this is not so when starting jet engines. Because of the starting characteristics of a jet engine, it is essential that the starter remain engaged not only until the engine has fired (which is at approximately 800 rpm) but also until the engine has reached a speed of revolution which will permit satisfactory engine acceleration without causing the engine to overheat. On the multijet airplane, the starter circuit becomes disengaged at approximately 2,700 engine rpm, and does so automatically to allow the pilot to give his undivided attention to the instruments and throttles.

The automatic starter disconnect feature is accomplished by utilizing a current relay as shown in Figure 1. This relay is a single-pole double-throw double-break relay that has had its coil replaced by a straight bus which carries the full starter current. It is set to pull in at approximately 500 amperes starter load and drops out when the load is reduced to approximately 200 amperes. The normally-open contacts are used to provide a hold-in circuit for the starter relays and, upon opening, de-energizes the starter. From the curves in Figure 2, it can be seen that as the engine speed increases, the starter-motor contribution to engine rotation decreases, with a resultant decrease in starter current. By simply adjusting the tension on the current relay's contact spring, the relay can be made to drop out at any predetermined engine rpm. The starter motor, therefore, becomes de-energized when its usefulness to the starting cycle is ended. Utilization of this drop-out feature is a primary advantage inasmuch as it permits "overlap starting." See Figure 3.

By the term overlap starting is meant the practice of beginning a starting cycle on one engine before the finish of the starting cycle of a previously started engine. Due to the fact that it takes approximately 30 seconds for the starter to accelerate the engine to firing speeds, it is possible for the pilot to utilize this time to work on another engine. This is precisely what the pilot has been able to do, thereby reducing the over-all time for starting all six engines. It was originally estimated that the very minimum time for starting six engines would be 15 minutes. However, by utilizing the automatic starter disconnect feature, the pilot has been able to start taxiing within five minutes from the time the first starter was energized. This represents a saving of several hundred pounds of fuel which is a very important item on this type of airplane and could very easily represent the difference between an incompleted and a completed mission.

Common Power Leads

The second main item that required consideration was that of utilizing common power leads for conducting power to and from the starter-generator. Originally the system used separate power leads for starting and generating purposes. Such a system is generally considered very satisfactory on most standard airplanes and was used on the initial control circuit on this airplane. However, after the complete control system had been "jelled," a weight survey of the system was made and it was found that the wire weight involved was way out of proportion to the value, or service the system rendered. Consequently, the circuit was redesigned to permit maximum utilization of the starter-generator power leads. To accomplish this, a switching arrangement was used to allow the use of the generator power leads while starting. This required the use of three 400-ampere relays and one *AN3025-2* differential reverse current relay per engine. Two of the 400 ampere relays (one starter relay and one generator relay) are located adjacent to the starter-generator while the other

Paper 48-239, recommended by the AIEE air transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 22, 1948; made available for printing August 30, 1948.

VICTOR B. HART is with the Boeing Airplane Company, Seattle, Wash.

The author wishes to thank the Boeing Airplane Company, Seattle, Wash., for permission to present these data.

Figure 1 (left). Main power distribution shield (typical for each wing)

Figure 3 (above). Typical starting sequence recorded during a normal engine starting run

starter relay and the reverse current relay are located at the electrical distribution center in the body of the airplane.

Operation of the momentary starter switch energizes the two starter relays, thus switching the power leads to the starter circuit. After these relays have become de-energized, the generator relay picks up to switch the power leads back to the generator circuit. Subsequently, as the terminal voltage of the generator rises to exceed that of the bus, the differential reverse current relay becomes energized to connect the generator to the main bus.

The success of such a switching arrangement is predicated on the ability to prevent both the starter and generator relays from becoming energized at the same time. Many different types of switching arrangements could be used to achieve this requirement, and, of several methods tried, none was as simple and direct as that shown in Figure 4. It consists of controlling the generator relay through the normally closed contacts of both the starter switch and the current relay while, at the same time, it prevents shunting of the current relay during the starting cycle by utilizing the reverse current characteristic of the *AN3025-2* relay.

The reliability of a control system that utilizes switching relays in the main power leads to the generator at first appears to be questionable. However, when balancing the possible additional risks that may be involved against the amount of weight saved, there can be no doubt as to the value of such an arrangement. In the final configuration, it was possible to save from 30 to 40 pounds of weight per engine by utilizing this control feature.

When multiplying this value by six (for a 6-engine airplane) it can be seen that the total weight saved per airplane represents a large percentage of the total weight of the entire electric system.

Automatic Equalizer Disconnect

Another item in the starter-generator control system is the incorporation of an automatic equalizer disconnect. On most multiengine-type airplanes, the generator equalizer is controlled normally through the generator switch, the equalizer circuit being connected whenever the generator switch is in its "on" or normal position. Should a generator in such a parallel system become disconnected either by its overvoltage relay or its reverse current relay or just due to the engine being shut down, and should it also fail to have its generator equalizer system disconnected, its equalizing circuit would effectively send a signal to the regulating systems of the remaining generators to call for a reduction in their output voltages. The magnitude of this voltage reduction is approximately directly proportional to the number of generators removed from the line and amounts to approximately three to four volts when four out of six generators are lost as power sources.

Inasmuch as it is a standard procedure

Figure 2. Typical engine rpm and current curves versus time during starting period of jet engine

Figure 4. Starter-generator control circuit

Figure 5. Generator equalizer circuit

1. Starter generator
2. Voltage regulator
3. Differential reverse current relay AN3025-2
4. Current limiter
5. Equalizer resistor
6. Equalizer cutout relay

for this type of airplane to reduce engine speed below 4,000 rpm (the lower limit for generator output) on all but two engines during a normal landing, it is most important that the available system voltage be maintained at its highest level. To insure that the main bus voltage will not be jeopardized by failure to disconnect a dead generator's equalizer circuit, the control for each circuit was transferred from the generator switch to an equalizer cutout relay (see Figure 5) which is controlled by the differential reverse current relay. Any time, therefore, that the reverse current relay becomes deenergized to remove its generator from the main bus, it will automatically deenergize the equalizer cutout relay to open its equalizer circuit.

TYPICAL FOR EACH GENERATOR EQUALIZER SYSTEM

Using a relay for control of the equalizer circuit has another advantage in that it can be located relatively close to the voltage regulator. This serves to shorten the lengths of the equalizer leads which not only reduces weight but allows for less lead resistance which means much better load distribution. This is borne out by the fact that the copilot has observed that the generator loads are distributed much more evenly than those encountered on other multiengine airplanes in which he has flown.

The remaining features of the control system, namely, overvoltage protection and indication, generator cutout due to either throttle cutoff or normal control, starter cutoff, and ammeter and voltmeter indication, have been purposely deleted. It was not intended that these features be discussed inasmuch as they are treated in much the same manner as those on reciprocating-type multiengine airplanes.

Conclusions

1. Incorporation of an automatic starter control system has made it possible to reduce the total engine starting time to a very minimum.

2. The utilization of common power leads for both starting and generating purposes has saved 215 pounds of wire per airplane.

3. Providing an automatic disconnect of the generator's equalizing circuit has allowed for maximum possible system stability during the loss of one or more generators.

Ground Power for Aircraft

JOHN H. BLANKENBUEHLER
FELLOW AIEE

Synopsis: The increasing use of electric apparatus on aircraft has brought about the need for rather large sources of electric power for these planes while they are on the ground without engines running. The development of these ground power units from the original storage batteries through the makeshift postwar era to the present highly specialized units is traced in this paper. Units from 5 to 60 kw now are used for this purpose. These units consist of portable engine driven sets as well as induction motor driven units for use in the hangars. These units must all be equipped with special voltage controls and with complete radio interference suppression. The larger units are furnished with a great variety of portability, some being self-propelled. These units must be built in 12, 28, and 120 volt direct current as well as 120-volt 400-cycle alternating current.

NEARLY all of the prewar airplanes were equipped with 12-volt d-c electric systems. They had a few instruments requiring electric energy, a few lights and an engine starter. The war brought about a great increase in the use of electric equipment on aircraft. Those planes developed during and after the war nearly all were equipped with 28-volt d-c systems. During and immediately after the war these planes were serviced on the ground by the use of battery carts containing either 12- or 24-volt storage batteries which in some cases could be switched from one voltage to the other. As a source of ground power these units had the usual maintenance problems attending the use of storage batteries.

In an effort to eliminate these maintenance problems, some operators coupled some of the generators developed for use on the aircraft engines to a small industrial engine and mounted the assembly on a cart, together with the necessary control, and used this as a source of ground power. These generators had been developed to run at a very high speed, too high for the usual industrial engine, and their shaft construction made the problem of coupling them to the engine very difficult. These units probably gave more trouble than the batteries.

Other operators converted conventional single operator arc welding generating sets, both motor and engine driven, from their usual constant current characteristics to a more or less constant voltage characteristic for this purpose. This was a makeshift operation since these generators were all designed for a much higher voltage than required and were equipped with differential compounding which was exactly the opposite of the compounding required for this purpose. These generators also had very high field currents and usually required two regulators in parallel in order to handle these field currents. The regulators rarely paralleled satisfactorily and quickly gave trouble.

Dry disk metallic oxide rectifiers such as the copper oxide, copper sulphide and selenium rectifiers have also been used as a source of the d-c power required. In general these units are much more bulky than the equivalent rotating generator. They also, of course, require a source of alternating current power supply which limits their portability. A rectifier must also have with it a transformer to step the line voltage down to the necessary rectifier input voltage, a saturated reactor or some equivalent means of controlling the voltage output of the rectifier, a d-c reactor to minimize the voltage ripple, as well as the necessary control and ventilation means.

The last two years have seen the rather general adoption of the rotating generator as a source of power for aircraft on the ground. The great majority of these generators are gasoline engine driven. The first units were built with a rating of about 4 kw but now the most popular size is a 15-kw unit. Other units are built in 5, 7.5, 30, 50 and 60 kw ratings. The great majority of these are 28.5-volt direct current. A few of them are dual voltage, that is, either 28.5 or 14 volts. Some of the units are motor driven and are portable for use in the hangar where electric power is available. Other units are motor driven and are arranged for location in a pit or tunnel beneath the apron of the airport. In these cases power is brought to the airplane on the ramp through a manhole or sunken access opening covered with a trap door.

A very few airplanes have been built with 400-cycle electric systems. Combination generating units supplying either 400 cycles or direct current have been built for airport servicing these types of planes together with the more standard d-c types. Some of the d-c airplanes have a few 400-cycle instruments on them and 400-cycle generating units are made to supply power for servicing these instruments.

A few 120-volt aircraft have been built but do not present any different problem in ground power equipment other than to require a generator of that voltage.

Most of the generating units are of the single-voltage 28.5-volt d-c type and the following discussion will largely refer to this type of set. Except for the smaller sizes (4 and 5 kw), the generators are usually separately excited, cumulatively compound. In general the exciters themselves are 120 volts so that they can in turn be used to supply power to floodlights when desired. The generators are all rated continuously at 50 degrees centigrade rise. The overload capacity of these generators depends on the type of prime mover driving them. The motor driven units, like most induction motor generator sets, will give 50 per cent overload readily. In order to keep the size, weight and first cost from being excessive, the engine driven units generally do not have such a high overload capacity.

Paper 48-240, recommended by the AIEE air transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted July 21, 1948; made available for printing August 12, 1948.

JOHN H. BLANKENBUEHLER is an engineer with both the Hobart Brothers Company and the Motor Generator Corporation, Troy, Ohio.

Figure 1. Constant current control diagram

They will usually give from 15 to 25 per cent overload. In a few cases 50 per cent overload can be obtained from them, but this is unusual.

All of these units are designed to use the standard carbon pile aircraft-type voltage regulator which is readily available at all aircraft service centers. These regulators will provide a voltage regulation of $\pm 1/2$ volt at 28.5 volts standard voltage. Some of the smaller units are arranged so that a throw of a switch or the reversal of the cable connecting the unit to the aircraft will operate to change the voltage supply to the aircraft from 28 to 14 or vice versa. Since it is standard practice to have one type of receptacle in the aircraft for 12 volts and another for 24 volts, automatic changeover of this voltage is readily feasible.

Although the constant voltage characteristic is by far the most popular, other characteristics have been developed to suit certain special applications. Since a constant voltage regulation in the generating unit does not mean a constant voltage in the aircraft because of the voltage drop in leads to the aircraft, systems have been developed to compensate for this lead voltage drop. Probably the simplest system is to connect the paralleling coil of the standard voltage regulator across some resistance in the load circuit of the generator, such as the commutating field coils and series field coils, and then to adjust the current in this paralleling coil so as to overcompound the regulator enough to compensate for the voltage drop in the leads going to the aircraft. From 4

Figure 2. Characteristic curves for jet engine starting

to 5 volts overcompounding can be obtained in this way. This also enables the operator to use much smaller leads going from the unit to the aircraft and thus these leads will be more flexible and less burdensome.

The starting of jet engines seems to require another type of voltage current characteristic. The jet engine starting motor is a series motor and of course the torque delivered by it is therefore proportional to the square of the current delivered to the motor. If a constant voltage power source is used the initial inrush of current to this motor will be very high (2,500 to 3,000 amperes) and as the motor increases in speed this current will of course drop off. This means that the gears, bearings, and all of the parts of the motor starting system must be large enough to stand the initial inrush torque. If the input current to the starting motor could be limited at start to a definite value and then kept at this value throughout the starting cycle, the mechanical parts of the starting system could be much smaller and therefore weight would be saved. A generating unit for this purpose has been designed with which the operator can preset the current to be delivered to the motor. This is done as is shown in Figure 1, by using two voltage regulators, one in the normal voltage regulating connection and the other with its coil acting as a current coil instead of a voltage coil. Instead of putting the full generator current through this coil it is usually connected across the generator field coils as shown. At any current which will excite this coil to the preset value the carbon pile operated by this coil will act to regulate the field current so as to maintain this current constant. During this period the voltage will be lower than normal and the voltage regulator will have its pile in the minimum resistance condition. As soon as the voltage reaches the normal value, the voltage regulator will take control from the current regulator and maintain constant voltage. Voltage regulation curves such as are shown in Figure 2 are readily obtained with this control system. In practice it is also customary to have an automatic control system short circuit the generator, thus reducing its voltage to zero prior to closing the circuit to the aircraft. Immediately after the circuit to the aircraft is closed the contactor short circuiting the generator opens and current flows through the starting motor at the predetermined value. As the starting motor speeds up, the current is maintained constant up to the usual 28.5 volts. Then the current decreases and at a preset cutoff point, a current relay acts to disconnect the power unit from the starting motor.

Figure 3 shows the circuit diagram of a typical ground power unit. The apparatus shown includes the generator with its exciter, the carbon pile voltage regulator together with a transfer switch, and a manually operated field rheostat. By this means the operator can transfer to manual adjustment of the generator's terminal voltage in case of failure of the voltage regulator. This is purely for emergency operation. In some cases, such as the one shown, the carbon pile of the regulator is paralleled by a fixed resistor in order to adapt the standard regulator to the field

Figure 3. Typical ground power unit diagram

Figure 4. Motor generator set for hangar service

Figure 5. 200-ampere set on dolly-type running gear

currents being used. Better voltage response to changes in loads have been obtained with the regulator in the main field circuit than can be obtained with the regulator in the exciter field circuit. Figure 3 also shows the ammeter and voltmeter normally mounted on the control panel together with the contactor, in the output lead to the aircraft, which is operated by a push button. In some cases manually operated circuit breakers are used on the smaller units. All units are equipped with overvoltage, reverse current and overload relays. In those cases where the voltage regulator is compensated for lead drop the overvoltage relay must also be arranged in a similar manner. This is easily done by putting another coil on this relay connected across a resistance in the load circuit. In some cases the control of the line contactor is interlocked with a relay in the aircraft or with the plug inserted into the aircraft receptacle so that power may not be connected to the aircraft prior to proper insertion of this plug.

Engine driven equipment must also have the necessary controls for the engine on the control panel. These generally consist of a tachometer of the vibrating reed type, an engine hour meter to indicate when the engine should be overhauled or serviced, and the usual water temperature and oil pressure gauges together with an ignition switch and some sort of throttle control. In most cases the throttle is controlled by means of a tumbler switch on the panel through a solenoid in the engine compartment. In this manner the engine can be run at idling speed or at full governed speed.

In some cases overspeed relays are provided as a matter of extra precaution. The most simple overspeed relay is a voltage relay across the exciter which operates to open the ignition circuit of the engine if the exciter voltage rises to an excessive value.

The 4 and 5 kw units generally have batteries as well as the engine generators to provide high peak currents for a short time. These units are also equipped with a relay to disconnect the battery from the output line when the generator is not running so that the battery may not be discharged accidentally.

All of these generating units must be equipped with adequate radio interference suppression. This is generally accomplished with small grounding capacitors at various points. A 0.5 microfarad capacitor is connected from each output terminal to ground, a 0.25 microfarad capacitor is connected from each brushholder of the main generator to ground, and an 0.1 microfarad capacitor is connected from each brushholder of the exciter and from the regulator of the engine's battery charging generator as well as the ignition coil to ground. A 10,000-ohm suppressor is used in the lead from the ignition coil to the distributor and similar

suppressors are used at each spark plug. In a few cases completely shielded ignition harness is used.

The small sets use a duplex number 1/0 cable from the generator to the aircraft. Duplex cables are provided as large as 4/0. These cables are terminated in a model *AN-2551* plug for the 28.5 volt units. The 12-volt systems have an *R-3081* plug on them. Some of the 30-kw units and all of the 50- and 60-kw units use the *Cannon 16553* plug with from three to six number 3/0 cables per polarity. A plug of this type meant to carry 1,500 amperes with 30 feet of cable connected to it consisting of 12 conductors each 3/0 in size presents a formidable handling problem. The cable alone will weigh 250 pounds. For this reason, aluminum cable is being used in some instances. At the present time it is difficult to obtain a very flexible type of cable and its low conductivity does not bring about any considerable gain.

Interesting as are the electrical problems encountered in the development of this equipment, the mechanical problems become almost as varied and noteworthy. The motor driven generating sets for hangar use such as shown in Figure 4, for instance, have all of the controls arranged so that any contacts which might create a spark are more than four feet from the floor. Likewise the air intakes at the end of the set are equipped with a duct raising the actual air intake to more than four feet above the floor. This is done to prevent the explosion of any vapors which might collect on the floor of an aircraft hangar. This unit as can be seen is also equipped with a special running gear which prevents turning of the wheels unless the tongue or draw bar is depressed.

Figure 5 shows one of the smaller 5-kw units which as noted before has the batteries on it to provide high currents for short times. This unit is mounted on a 3-wheel dolly and can be towed or pushed to its destination. Figure 6 shows the most popular 15-kw unit on a 4-wheel running gear for towing. Such a running gear is equipped with parking brakes and the unit also has large compartments at the sides for storage of tools and cable. Figure 7 shows one of the self-propelled units in which the engine may be used to either drive the generator or propel the entire unit wherever desired. This unit may also be used for towing the smaller planes requiring up to 3,000 pounds draw-bar pull. Figure 8 shows a smaller variety of this self-propelled unit. Both of these types are developed with a great variety of accessories such as floodlights, fire extinguishers, and so forth.

Figure 9 shows a 60-kw unit consisting of two 30-kw engine driven generating sets arranged for either separate or parallel operation. This unit is equipped with one *AN-2551* plug with 20 feet of cable and one *Cannon 16553* plug with 30 feet of 12-conductor cable on each side. Storage of this cable in an accessible position became a real problem here. A truck of this sort may also be used to tow rather large aircraft requiring a draw bar pull of 8,000 pounds or less. This unit is also equipped with a carbon dioxide fire extinguishing system for connection to the plane.

Two 50 pound CO_2 cylinders are manifolded to a hose reel on the truck. The hose from the reel is plugged into the aircraft and piped through the CO_2 distribution system in the aircraft. This avoids discharging the cylinders in the aircraft in case of a ground fire. This unit and all of the other units are normally provided with one or several 2.5 pounds CO_2 hand extinguishers.

Table I shows the ground power requirements of the various airplanes now most commonly used, expressed in amperes for the 28.5-volt system. The tabulation indicates roughly the apparatus using the current and the current requirements are divided into two classes, continuous and intermittent. A continuous requirement is that which may be on during the warm-up, functional testing, and passenger loading. The intermittent loads are those on for a few seconds to a few minutes during this time.

Table I is an oversimplification of a terrific mass of data kindly given me by all of the aircraft manufacturers and a number of the operators. Because of the different equipment used by the different airlines it is probable that none of the data is exactly correct for any particular airplane. It is, however, a good average interpretation of the data available and is representative enough to show the loads which are being encountered in present-day operations. It is interesting to notice that in general the more recently the plane was developed the more electric power it requires. It is interesting to note also that the modern long-range aircraft require 30 to 50 kw and the modern short-range aircraft require 8 to 15 kw. Regardless of these indications many of these aircraft are being serviced with 5-kw generating sets and battery carts.

The trend at the present is definitely toward larger units and seems to be toward a combination of various other functions such as fire extinguishing together with the electric power generation on one self-propelled unit. Newer units are arranged to provide more than one voltage and in some cases with both direct current and 400-cycle alternating current.

Discussion

Stanley Taborsky (Glenn L. Martin Company, Baltimore, Md.): The author's paper is very interesting, and the writer who has had ten years of experience with the ground power requirements of commercial and

military airplanes, wishes to supplement this information with additional data which may be of interest.

As Blankenbuehler explained, portable 200-ampere hour battery carts were in extensive use prior to the recent conflict and were quite capable of starting engines and supplying sufficient power for the limited amount of preflight test required. Since that time the very large increase in electric loads in aircraft with associated power plants of unprecedented power made it necessary to provide external ground power equipment of larger capacity. Our first experience was with metallic rectifiers of the magnesium-copper-sulphide type and others. These units have excellent engine starting characteristics but very poor voltage regulation. In addition, inclement weather conditions have a deleterious effect on the rectifier elements which make it necessary to frequently replace the rectifier stacks. It was therefore decided to use motor-driven generators for this work, and since equipment of this type with the desired operating characteristics was not commercially available, a standard 200-ampere motor-driven arc welding machine was modified for this purpose with a voltage regulator, reverse-current relay, circuit protection, and remote control.

This unit was standardized and the armed services found it satisfactory for their activities in this country and abroad, for use on medium size airplanes such as the *PBM*, *A30* and *B26*, until commercial equipment became available.

External ground power equipment is used by airplane manufacturers for the following functions:

1. Engine starting.
2. Functional tests of the electric system, including the adjustments of limit switches on electric motor-driven trim tabs, cowl flaps and oil cooler flaps.
3. Operation of radio, radar, and other electronic equipment.
4. Occasional charging of the ship's batteries after installation.

To satisfactorily accomplish these functions it was found necessary to provide equipment to meet the following general specifications:

1. Sufficient capacity to start engines in a minimum amount of time in order to prevent engine starter burnouts. As is known, these starters are made for a very low duty cycle in order to conserve weight and prolonged operation is therefore objectionable. In addition, the equipment must maintain a voltage level above the dropout voltage of the starter relay on the airplane during engine starting to prevent chattering and subsequent failure of the relay.
2. Voltage regulation (±2 per cent) comparable to the electric system on the airplane so that mechanical controls can be properly adjusted and tested to insure flight integrity.
3. Minimum noise level and ripple not to exceed 1 per cent for radio, radar, and electronic tests.
4. Reverse-current control for use in charging ship's batteries.

Our experience in these problems has dictated that commercial aircraft and small military airplanes should be serviced with external ground power equipment having a continuous rating of 300 amperes at 28.0 volts with a 15 seconds overload rating of 600 amperes at not less than 18 volts and a 2 minutes overload rating of 400 amperes at not less than 24 volts direct current.

Heavy military airplanes require the use of equipment with a continuous rating of 600 amperes at 28.0 volts with a 45 seconds overload rating of 2,100 amperes at not less than 18 volts, and a 2 minute overload rating of 1,000 amperes at not less than 24 volts.

Additional desired features are remote control, over-voltage protection, line drop compensation, and overload protection. With regard to over-voltage protection, I wish to point out that voltage regulators of the carbon-stack type have been known to stick thereby causing excessive voltage and considerable damage to such equipment as storage batteries, radio equipment, and lighting circuits on the airplane. Separate generator field exciters are necessary to provide quick voltage recovery during shock loads and the use of auxiliary batteries to supplement this equipment is objectionable from a maintenance point of view. The units must be rainproof and portable, with provisions for towing with a truck. Self-propelled units are also desirable in some activities. Since it is not feasible to provide electric power outlets in all locations for the operation of this equipment, it is necessary to provide gasoline driven units for use in remote locations.

Jet engines must be started as quickly as possible since prolonged ground operations curtail flight time due to the large fuel consumption of the engines and the small capacity of the fuel tanks. The 600-ampere equipment used for heavy military airplanes is therefore operated in parallel to provide the capacity to start jet engines every 15 seconds on multiple-engine ships. It usually takes about 45 seconds before a jet engine can be cranked to the firing speed, at which time the starter is de-energized. However, at the end of 15 seconds, the inrush current has diminished to such a value that the next engine can be started without overloading the two external power units operating in parallel. This procedure is continued until all engines have been brought up to firing speed with the equipment installed at the run-way to allow for immediate take-off.

We have had no experience with the constant current method of starting airplane engines. It is, however, understood that the Services will specify this type of equipment for future applications at which time operating data on its use will be presented.

The writer sincerely hopes that this information, together with Blankenbuehler's excellent paper, will stimulate manufacturers' interest and result in the production of standard equipment capable of satisfying the requirements of airlines and aircraft manufacturers.

Rural Distribution Voltages

WADE M. EDMUNDS
MEMBER AIEE

GLENN B. ROLOSON
NONMEMBER AIEE

AT THE TIME the Rural Electrification Administration (REA) was established by executive order in May 1935, the voltages on rural distribution systems covered a wide range and included some of the multigrounded Y systems that are in use today. Single bushing 6,900-, 7,200-, and 7,620-volt transformers had been made available by the manufacturers.

The REA made an extensive study of the voltages that were then in use and in December 1936, issued suggested specifications for 12,000/6,900 volt Y-multigrounded neutral distribution circuits. This selection was based largely upon Tennessee Valley Authority practice and the fact that transformers were available. Within a short time the REA's suggestions were changed to the present 12,470/7,200-volt Y-multigrounded neutral specifications.

After lines had been constructed to serve a definite area, there was a great demand for service outside that area with the result that many additions were made which had to be served over the original lines or modifications of them.

The earlier REA-financed systems had consumptions on the order of an average of 50 kilowatt-hours per month per consumer. Up until the last few years most lines were designed on the basis of approximately 100 kilowatt-hours per month per consumer. However, the consumption per consumer has been steadily increasing until now consumptions of 300 and 400 kilowatt-hours per month per consumer are not unusual and the end is not yet.

The system operators have had to meet this load growth by installing voltage regulators, increasing the number of phases, and increasing the size of conductor. There is a limit to the number of regulators that can be cascaded and the amount of rephasing that can be done. There is also an economic limit to increasing the size of conductor. Increasing the size of conductor reduces the resistance but reduces the inductance only a little. For lines with reduced size neutral, the curve of admittance plotted against pounds of conductor begins to flatten out above number 2 copper conductivity phase wire. With some conductors, the cost per mho for 4/0 conductor is more than double that of number 6.

There is an increasing demand for service in sparsely settled areas where the distances to be covered are much greater than on systems heretofore constructed. More than usual economy is required to construct these systems.

It appears that some departure from the present standard distribution voltage is required. As early as 1937 the REA considered the possibility of using 22,300/-13,200 volts as another multigrounded Y voltage standard and the idea of using this or a slightly higher voltage has come up from time to time.

The load capacity of a distribution system varies as the square of the system voltage. A 23.9/13.8 kv Y-connected multigrounded system would have 3.67 times the capacity of a 12.47/7.2 kv system using conductors of the same size. A uniformly loaded line at 23.9/13.8 kv may be extended 90 per cent further and serve 3.67 times the area of a uniformly loaded line at 12.47/7.2 kv with the same size conductors. This takes into account the loads on the additional 90 per cent of line.

About 1942 a co-operative in Minnesota purchased approximately 50 miles of 23.9/13.8-kv Y-connected multigrounded transmission line with some 13.8-kv transformers (15-kv insulation class) transformers installed along the line. Most of these transformers had been installed in 1916. After the acquisition of this line, the co-operative began buying transformers to be used on extensions to serve farmers and in 1944 there were some 150 or 160 13.8-kv transformers (15-kv insulation class without lightning arresters) connected on this line and the manager stated in 1944 that in the two years the co-operative operated the line, not a single transformer had been lost due to lightning and that the operating experience with the transformers had been excellent. An REA field construction engineer reported on this line in April 1947 and from what he could learn, no more 13.8-kv transformer failures occur than with the 7.2-kv transformers on other parts of the co-operative's system. Some of the 23.9/13.8-kv line has been absorbed into the 12.47/-7.2-kv portion of the co-operative's system so that there are now 80 miles of 23.9/13.8-kv line with 70 transformers.

The estimated costs of two proposed projects in Colorado are shown in Table I.

Increasing the distribution voltage to

Table I

	Project A	Project B
Primary miles	387	208
Consumers	434	238
Cost using 12.47–7.2 kv	$702,672	
Cost with transmission line and substations added	$559,756	$625,000
Cost with 23.9–13.8-kv distribution*	$475,565	$415,000
Per cent saving 23.9–13.8 kv over 12.47–7.2 kv plus transmission	15	34

* 15-kv insulation class transformers with the same lightning arresters as if the transformers were connected in delta.

Paper 48-241, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 12, 1948; made available for printing August 26, 1948.

WADE M. EDMUNDS and GLENN B. ROLOSON are both with the engineering division of the Rural Electrification Administration, Washington, D. C.

23.9/13.8 kv does not materially affect conductor separation although it would decrease the maximum allowable span length to a small extent. Apparently the National Electrical Safety Code permits the same ground clearance for single-phase sections of 23.9/13.8-kv systems as on present systems but, however, an additional 2-foot ground clearance is required on multiphase sections of 23.9/13.8-kv systems.

No REA-financed systems have been completed as yet using 23.9/13.8-kv distribution. The transformer manufacturers do not recommend nor guarantee their 15-kv insulation class transformers for this service. Their objections are based mainly on these two points:

1. On a 13,800-volt 15-kv insulation class transformer the insulation between the winding and the case was designed for the electrostatic voltage of 7,968 volts. The phase voltage of 13,800 would occur only between the winding and case under faulted conditions. When this transformer is connected between a phase wire and ground on a 23.9/13.8-kv Y-connected system, the voltage between the winding and case always would be 13,800 volts.

2. On a 13,800 volt 15-kv insulation class transformer connected between a phase wire and ground on a 23.9/13.8-kv Y-connected system, a fault to ground on one phase would cause an excessive voltage rise on the other phases which would damage the transformers.

The effect of line-to-ground faults on the voltage of the unfaulted phases was calculated by the methods given in the Electrical Transmission and Distribution Reference Book. The calculations were only for the substation and the distribution line without the transformers. According to these calculations, the voltage rise for number 6 conductor with the fault at a considerable distance from the substation was approximately 58 per cent. It is realized that the calculations were for lines which are not comparable to distribution lines built to REA specifications, but it is likely that calculations of this kind have tended to create the impression that the effect of the neutral shift is greater than is actually the case.

In order to determine the voltage rise due to neutral shift, it was decided to place line-to-ground faults on one phase and measure the voltage on the unfaulted phases on an existing system in an area of high ground resistivity. The system selected for the tests was that of the Southside Electric Cooperative, in the vicinity of Blackstone, Va.

A 50-ampere oil circuit recloser with the current coil short-circuited out was used in making the line-to-ground faults. A type *PM 13*, 6-element oscillograph was used to record the voltage on the unfaulted phases and the fault current. Ground resistances were measured with a model *251* Vibroground.

The oil circuit breaker was connected between a phase wire and the neutral which was connected to a ground rod. A current transformer was placed in the lead from the oil circuit breaker to the neutral. Potential transformers were connected between phase wires and neutral. The fault current reading was obtained where the fault and oscillograph were in the same location but in some instances it was too large to get a reading.

The first series of tests was made on lines feeding from a 66/12.47/7.2-kv 5,000-kva substation. In these tests the resistance of the neutral to ground ranged from 22 to 24 ohms at the location of the tests. Oil circuit reclosers in the distribution circuits limited the duration of the faults.

In test *A*, the fault was made at a distance of 11.9 miles from the substation. This mileage consisted of 5.9 miles of 3-phase, 1/0 copper-phase wires with number 6 neutral and 6.0 miles of 3-phase, number 4 phase wires with number 6 neutral. The recorded voltage rise on the unfaulted phases at the location of the fault was 14 and 18 per cent and lasted a maximum of 15 cycles.

In test *B*, the fault was made at a distance of 26.1 miles from the substation. This mileage consisted of 5.9 miles of 3-phase, 1/0 copper-phase wires with number 6 neutral, 9.6 miles of 3-phase number 4 phase wires with number 6 neutral and 10.6 miles of V-phase* number 6 phase wires with number 6 neutral. The fault current was 120 amperes, and the recorded voltage rise on the unfaulted phase at the location of the fault was 23.5 per cent and lasted a maximum of 38 cycles.

In test *C*, the fault was made on a single-phase tap at a distance of 22.1 miles from the substation. This mileage consisted of 5.9 miles of 3-phase 1/0 copper-phase wires with number 6 neutral, 9.6 miles of 3-phase number 4 phase wires with number 6 neutral and 6.6 miles of single-phase number 6 phase wire and number 6 neutral. The recorded voltage rise on the unfaulted phases at a point 10.6 miles on the V-phase number 6 phase wires with number 6 neutral line beyond where the single-phase tap left the main line, was 7 and 20 per cent respectively, which lasted a maximum of 7 cycles.

In test *D*, the fault was made at a distance of 11.9 miles from the substation. This mileage consisted of 5.9 miles of 3-phase, 1/0-copper-phase wires with number 6 neutral and 6.0 miles of 3-phase number 4 phase wires with number 6 neutral. The voltage was recorded at a point beyond the fault and at a distance of 26.1 miles from the substation. The line beyond the fault to the point where the voltage was recorded consisted of 9.6 miles of 3-phase number 4 phase wires with number 6 neutral and 10.6 miles of V-phase, number 6 phase wires with number 6 neutral. The recorded voltage rise was 12.5 and 30 per cent respectively, and lasted a maximum of 18 cycles.

The second series of tests was made in an area about 90 miles from the first series of tests on lines feeding from 13.2/-12.47/7.2-kv 600-kva substation. In these tests the resistance of the neutral to ground was 25 ohms at the location of the tests.

In test *E*, the fault was made at a distance of 12 miles from the substation. This mileage consisted of 3-phase number 6 phase wires with number 6 neutral. The fault current was 86 amperes, and the recorded voltage rise on the unfaulted phases at the location of the fault was zero per cent on both phases. Actually, a slight decrease in voltage was shown.

In test *F*, the fault was at a distance of 20 miles from the substation. This mileage consisted of 18 miles of 3-phase number 6 phase wires with number 6 neutral and two miles of V-phase number 6 phase wires with number 6 neutral. The voltage was recorded at a point 12 miles from the substation on the 3-phase section of the line. The voltage rise on the unfaulted phase was 0 per cent. Actually, a slight decrease on voltage was shown.

In the first series of tests the voltage rise on the unfaulted phases, due to a line-to-ground fault, ranged from seven per cent to a maximum of 30 per cent. The effect of the fault current on the regulation of the 66-kv line supplying the delta connected, 5,000-kva substation was probably negligible so that practically the full effect of the neutral shift was apparent. Also, the *IZ* drop in the neutral was larger than would have been the case had the neutral been the same size as the phase conductors.

In the second series of tests there was no voltage rise on the unfaulted conductor due to a line-to-ground fault. This can probably be explained by the fact that the power is supplied to the delta-connected 600-kva substation over a 13,200 volt line and that the regulation,

* V-phase refers to open Y circuit.

due to the fault current, cancels out the voltage rise produced by the neutral shift. Also, the IZ drop in the neutral was not as large as would have been the case had the neutral been of less size than the phase conductors.

The foregoing tests were made in areas of comparatively high ground resistance. These tests did not show as much neutral shift as had been calculated for bare lines without taking into account the constants of the system supplying power to the cooperative's substation.

Weighing the need in some areas for a considerably higher distribution voltage that would be economical against the possible hazards of equipment failure, it has been decided that some construction at a distribution voltage of 23.9/13.8 kv is warranted at this time. Two projects have now been approved for this type of construction, one in Arizona and one in New Mexico.

The Arizona project will consist of 284 miles of distribution line to serve 365 consumers. The distribution voltage is 23.9/13.8 kv. The first section, 125 miles to serve 174 consumers, is under construction. The area farthest from the source of power is at a distance of 70 miles. The distribution transformers to be used on this system are 13,800-volt transformers of the 15-kv insulation class.

The project in New Mexico will consist of 166 miles of distribution line to serve 248 consumers. The farthest extremity of the project from the substation is 76 miles.

Consideration is being given to a new distribution transformer design which will have insulation somewhat higher than the 15-kv class.

The performance of the two types of transformers will be watched closely after construction is completed, and tests made to determine which is more satisfactory.

Conclusion

A higher distribution voltage for use in rural areas is definitely needed where farms are widely separated and kilowatt-hour consumption will be substantial. Use of the 23.9/13.8-kv system is, of course, nothing new but in order that construction costs be within limits of feasibility, a substitute for the presently available 25-kv class distribution transformer must be found. A voltage rise of 30 per cent during a line-to-ground fault, lasting 18 cycles, does not appear excessive, and it is believed worthwhile to install 15-kv class transformers on an experimental basis.

Discussion

W. A. Sumner (Westinghouse Electric Corporation, Sharon, Pa.): The paper by Edmunds and Roloson indicates that there is still a field for pioneering work in rural electrification. In order to produce transformers correctly designed for this new and sparsely settled area where the present voltage appears to be inadequate, the manufacturers need as much factual data as possible. The tests and applications reported in this paper, while limited in number, provide a contribution to this subject and deserve consideration.

The authors are correct in stating that "more than usual economy is required to construct these systems." This includes, as a considerable portion of the first cost, the distribution transformers. While the investment in transformers must be kept as low as possible, it is also essential that their design be adequate for these more exposed areas so that the cost of operation and maintenance is held within economical limits.

In attempting to select a transformer for this service, the authors have explored the possibilities of using existing transformers. Here they are confronted with the fact that the present 13.8-kv (15-kv class) distribution transformers are not designed for this service, and, therefore, cannot be guaranteed for it by the manufacturers. On the other hand, if these transformers are designed on existing 25-kv parts, which are, generally speaking, of the small power class, the cost becomes prohibitive. What is needed is a new transformer designed for this specific purpose.

Care should be used in the interpretation of the tests reported in the paper. While the maximum overvoltage developed in these tests cannot be considered an excessive value, it should be realized that this materially affects the design of the protective devices for the transformer as they will be called upon to operate and restore line voltage conditions when the voltage is 130 per cent of normal 13.8-kv line voltage.

As to evaluating the prolonged and apparently successful performance of the 13.8-kv (15-kv class) transformers of the 1916 vintage, care should be used as this experience does not agree with that of some others who have tried this type of application. In the absence of detailed data, the insulation design of these units remains an unknown factor. The actual insulation design used obviously is a very important point in an analysis of this kind. These units were probably equipped with relatively small bushings in keeping with the general practice of that time. With the low flashover characteristics of these bushings, it is to be expected that transformers would receive relatively good lightning protection at the expense of an abnormal number of fuse outages. This is the usual experience, and it is felt that the data on outages should be included to enable complete evaluation of the performance of these transformers. The proposed project, involving 13.8 (15-kv class) transformers of current design, will provide much valuable field information, but it will take time to secure sufficient data to judge the life expectancy of such designs under these conditions.

In all these cases, the apparently successful operation under the limited conditions enumerated is made possible by the safety factors used in the design. In selecting these values, the manufacturers take into account, among other things, those elements necessary to produce a satisfactory length of life, and we do not feel that they are excessive when one considers the length of life which is normally expected of distribution transformers. In any event, these factors are not matters for standardization and are subject to possible change as manufacturing experience and field data are accumulated.

A more rational approach, in which a specification is drawn up based upon the operating needs for this specific application, seems desirable. We have, in fact, been asked by some of the utilities to furnish a transformer of this nature for a similar application, and we have supplied for a number of years, for a special industrial application, a transformer which has an insulation level intermediate between the 15-kv and 25-kv classes. Field experience with these transformers, covering some 18 years, has been very successful.

While this meeting is not a suitable occasion for drawing up specifications, it is suggested that the solution to this problem be worked out in a manner similar to that of the present successful 7,200-volt rural transformers. In the interests of standardization, it is proposed that consideration be given to rating the new transformer at 25,000 grounded Y/14,400-volts, using the existing EEI-NEMA standard high-voltage rating of 14,400/13,800/13,200/12,870 (12,540 reduced capacity). As to kilovolt-ampere ratings, it is not economically feasible to build a unit smaller than 5 kva at this higher voltage. As an approach to the problem of establishing the insulation test, it is recommended that considerations similar to those used in setting the test for the present 12,470 grounded Y/7,200-volt rural transformer be followed. In these transformers, the applied voltage test is omitted and an induced potential test of 26 kv is specified, this test to be made with the neutral grounded. This test places a stress to ground on the insulated end of the winding of 26,000 compared with 34,000 volts on the standard 2-bushing transformer. This suggests that these units should be designed for an induced potential test of approximately 40 kv. The resulting stress to ground on the insulated end of the winding of 40,000 volts compares with 50 kv on the present 25-kv class standard distribution transformers. These transformers should be designed to take full advantage of the contemplated multigrounded service, including the use of only one high-voltage bushing.

and with the other high-voltage line lead and the low-voltage neutral permanently grounded to the case, and should make use of existing highly tooled rural transformer parts insofar as feasible.

Harry N. Stafford (Rural Electrification Administration, Washington, D. C.): Since the writing of the paper one RRA-financed system using the 23.9/13.8-kv distribution voltage has been energized. This system is owned by Navopache Electric Cooperative, Inc., and is located in the eastern portion of Arizona in a mountainous region at a mean altitude of 7,500-foot elevation. When this system was first conceived, it found that it would not be possible to use the standard 12.5/7.2-kv distribution because of the long distances involved, nor was it possible to justify economically, the use of transmission lines because of relatively low consumer density. Hence it was decided to use a higher distribution voltage. This system has only been in service a few months and some refinements in design are anticipated when we have had more operating experience. There are presently 130 distribution transformers of the 15-kv insulation class installed and no failures of these transformers have occurred, although the system has been exposed to a portion of a very severe lightning season.

Steps have been taken to reduce the anticipated neutral shift and accompanying high voltages to a minimum under fault conditions. Every pole is provided with a ground tied into the system neutral which has resulted in a resistance of neutral to ground of approximately 4 ohms which is considerably lower than the 22 to 24 ohms measured in the test made on the Virginia system as described in the paper. Special attention has been given to substation grounds and neutral connections in order to reduce neutral resistance to a minimum. It is the observation of the writer after conducting preliminary tests on this 23.9/-13.8-kv system that little or no trouble is anticipated from neutral shift phenomenon.

The following is the voltage rating of equipment and devices used on this system:

1. Pin-type insulators, 22-kv class—95 kv dry flashover, 65-kv wet flashover.
2. Sectionalizing fuse—25-kv rating.
3. Distribution transformers up to 50 kva—15-kv insulation level.
4. Transformers 50 kva and over, including substation transformers—25-kv insulation level, minimum.
5. Lightning arresters, 15-kv rating, expulsion type.

One of the principal limitations of this type system is that there is currently no oil circuit recloser available for use on the 3-phase line which is comparable in cost to those used on existing REA systems of the standard 12.5/7.2-kv voltage.

R. F. Quinn (General Electric Company, Schenectady, N. Y.): The material in the authors' paper is valuable to those interested in rural power systems because both the tests and the cost figures add two important items to the store of information available to the system designer.

It is felt that the cost figures shown in Table I of the author's paper merit the following observations.

Project A

The figures under project "A" indicate that total cost serving the load with 12.47/-7.2-kv distribution and multiple substations and transmission is lower than total cost serving the load with one supply point and 12.47/7.2-kv distribution. This same trend is indicated by a similar economic study made less than a year ago.[1] This latter study, however, was based on greater load areas.

It is interesting to note that the authors show a lower cost for serving the same load area with 23.9/13.8-kv distribution from one source. It is probable that the cost is lower in this case because transformers and lightning arresters of substandard insulation class are used.

Project B

The figures under project "B" also show a lower cost using 23.9/13.8-kv distribution than using multiple substations and 12.47/-7.2-kv distribution. However, no figure is given for the case of one source and 12.47/-7.2-kv distribution. A figure for this latter condition would be interesting and would complete the picture.

Projects A and B

The comparative figures between projects "A" and "B" illustrate a broad principle of system economics as follows. It is fundamental that as a system grows in load density, area, or both, a given distribution voltage becomes outgrown and it becomes necessary to provide transmission or subtransmission and thereby break the area up into smaller units in order to use the same distribution voltage.

Therefore, as the load and distance increase, the system using transmission and substations should look better compared to higher voltage distribution. The per cent savings indicated for projects "A" and "B" bear out this principle very well. That is, project "A" having greater load and distance shows less advantage for higher voltage distribution than project "B".

If the load and distances were to increase in project "A", this saving in favor of 23.9/-13.8-kv distribution would vanish. As load continued to grow the saving could be in favor of subtransmission and substations and 12.47/7.2-kv distribution.

System Design and Continuity

A very important consideration that must always be factored in distribution system design is continuity of service. From the viewpoint of continuity of service, feeders must be kept reasonably short and multiple sources of supply must be provided. From a practical operating standpoint, many engineers who have studied rural systems feel that feeders should not be longer than 25 or 30 miles and that substations should generally not be larger than 1,000 to 1,500 kva each.

Adequate voltage conditions and reasonable losses are easily obtained using these feeder lengths and these substation sizes. Therefore, if continuity and general system operating considerations indicate these feeder and substation limitations, and if with these limitations, voltage and loss conditions are satisfactory using 12.47/7.2-kv distribution, there appears to be no requirement for using higher distribution voltage for the general case.

REFERENCE

1. WHAT SIZE SUBSTATIONS FOR ECONOMICAL RURAL POWER SYSTEMS?, R. F. Quinn, N. M. Neagle. *Distribution Magazine*, General Electric Company (Schenectady, N. Y.), January 1948.

E. A. Link (Rural Transformer and Equipment Company, Milwaukee, Wis.): Edmunds and Roloson are to be complimented on their paper for presenting progressive thinking on higher distribution voltages for rural lines. Much is to be said in favor of higher distribution voltages, both from the standpoint of wider consumer coverage and increased loads. In Europe, the economics of higher distribution voltages have been definitely proved in rural areas and these higher voltages have been used for many years. Almost conversely, the same problem in Canada, where the supplying of loads to customers spaced two per mile has been solved by limiting the amount of load demand supplied to each customer. Devices are used in Canada to relieve the system of load that exceeds approximately 7 kva demand per customer. In this way, reasonable sizes of conductors and reasonable numbers of regulators keep the cost per mile within economic limits.

It is our feeling that since the problems of load growth in the United States are already upon us in that in certain areas, definite steps must be taken to relieve the situation. We feel sure that the American public will not be content to live under a limited peak demand of power consumption and that our thinking must now be projected in a manner described by the authors.

The load growth on existing rural lines has exceeded all expectations. From a service standpoint, we have been going around in circles, trying to keep pace with the growing demands of the rural consumer. Problems of voltage regulation and system capacity are common problems to our co-operatives. Higher distribution voltage is a logical answer to many of these problems. As the paper points out, good economics can be realized in going to higher voltages on systems now requiring increased conductors or regulators brought about by increased load growth. The problem of converting from a normal 12,470-volt system to a 23,900-volt system may relegate the use of 23,900-volt distribution to new areas but it is also possible to gradually make this conversion by running a dual voltage system with autotransformer tie-ins. It seems quite reasonable that new systems in low load concentration areas should be laid out with consideration to the 23,900-volt distribution with the possibility of justifying the addition of the remote and hard to serve customers.

As transformer manufacturers, we believe that the obstacles of insulation pointed out by the writers can be overcome. In fact, the margin of safety of insulation brought about by the use of improved materials and design has been steadily increased over

the last few years. Actual test indicates that present 15-kv class transformers are much closer to 25-kv class and in addition, impulse breakdown levels of lightning arresters are now much lower than earlier devices, thereby giving a very comfortable margin of safety which could be extended to the 25-kv class.

Another major problem in the use of 23,900-volt distribution is overload protection and isolation of the individual transformer. Recent developments have opened a new field in the overload protection of transformers so that this may now be accomplished on the primary side of the transformer. Conventional fuses previously used for primary protection of transformers had time current characteristics that would not follow the heating characteristics of the transformer. These new overload devices, however, will accurately follow the overload heating capacity of the transformer, as well as co-ordinate with secondary overload devices and primary sectionalizing devices.

The over-all object of 23,900-volt distribution is cost savings to the ultimate user. It is quite possible that the reasoning used in the article under discussion will effect savings not only in the sparsely settled areas but also in the areas loaded beyond the designed line capacity.

The use of 23,900-volt distribution offers a new challenge to operators, as well as manufacturers, and a satisfactory answer is almost sure to be found by close co-operation between both parties.

J. C. Cunningham (Westinghouse Electric Corporation, Pittsburgh, Pa.): This discussion will be confined to the voltages which occur during faults and their effect on the application of protective devices.

The authors calculated 58 per cent voltage rise for a line with 6A conductors by methods given in chapter 15 of the Westinghouse Electrical Transmission and Distribution Reference Book.[1] Without more information on the line I cannot check their figure exactly but it appears that they must have used the curves in this chapter which include the effect of zero-sequence resistance but neglect positive and negative sequence resistance. For a circuit using 6A conductors R_1 and R_2 are not negligible because the resistance is approximately three times the reactance. However, Table 2 of chapter 15 gives formulas which include all resistances. Based on these formulas a line of REA configuration with several miles of 6A phase and neutral conductors and 2,500 meter ohms ground resistivity would experience 26.5 per cent voltage rise during a single-line-to-ground fault instead of the 58 per cent mentioned in the paper.

Rigorous calculation of fault voltages on a multigrounded 4-wire circuit is quite laborious although a relatively accurate workable method has been developed.[2] For the purpose of applying apparatus to rural distribution circuits the formulas in Table 2 of chapter 15 are probably adequate even though they assume transposition of the line (contrary to REA practice).

Following the tests which REA conducted at the Southside Electric Cooperative we prepared a report which compared these test results with values we calculated by a

Figure 1. Voltage to neutral of phase 2 and 3 caused by fault between phase 1 and neutral on multigrounded circuit

The numbers following the voltage designation indicate ground resistivity in meter ohms. The neutral conductor is two sizes smaller than the phase conductors indicated by the abscissa except for the curves marked 6A neutral

Phase rotation is 1-2-3

method which assumes that the resistance of connections between neutral and ground is zero. Even though the local ground resistances were quite appreciable, the test values of voltage checked very closely with the calculated values. Based on this close agreement we concluded that voltages on multigrounded REA circuits could be estimated with reasonable accuracy on this basis, if the fault were at least several miles away from the substation.

In order to obtain a more general picture of fault voltage magnitudes the curves of Figure 1 were plotted.

They apply only where the following assumptions are valid:

1. The source of power is grounded and its impedance is negligible by comparison with line impedance to the point of fault.
2. The fault is far enough from the source that the resistance between neutral conductor and ground, and other end effects can be neglected.
3. Ground resistivity is uniform.
4. Conductor size is uniform between the fault and the source.
5. The neutral conductor is two wire sizes smaller than the phase conductor (except for the curves marked 6A neutral).
6. The line configuration is per drawing $C1_{5/4}$

The number of circuit conditions covered by the calculations and tests described before is insufficient to draw final conclusions. However, it appears certain that voltages between phase and neutral conductor may frequently reach 130 per cent of the substation voltage and occasionally approach 140 per cent. An allowance must also be made for increase in the substation voltage above normal at light load. All in all it appears that voltages of 18–19 kv might be encountered frequently and even 20 kv might be exceeded occasionally on a 13.8/23.9-kv multigrounded system. It is significant that the ratio 20/23.9 kv corresponds almost exactly to the usual ratio of lightning arrester rating to line voltage for effectively grounded systems.

Lightning arresters are normally selected on the basis of the maximum phase-to-neutral voltage which may occur during any kind of fault. This is because of the possibility that a lightning arrester may discharge on one phase during a solid ground on another phase and thereby encounter recovery voltage corresponding to the fault condition. It must be recognized that a fault will not occur every time a lightning arrester discharges and that not every fault will cause the maximum fault voltage.

In addition lightning arrester performance will vary considerably with the severity of lightning exposure, system recovery voltage characteristics, and manufacturing variation in the lightning arresters themselves. For these reasons 15-kv lightning arresters may not have an excessive failure rate in some 13.8/23.9-kv installations but may be unsatisfactory in others. One must also consider that loss of transformer surge protection is probably more serious than the loss of the lightning arresters themselves. This would be especially serious in the low-density load areas for which these systems are contemplated because of greater exposure and the high cost of patrolling.

If 13.8/23.9-kv distribution is going to be needed frequently, careful consideration should be given to the development of a new distribution-class 20-kv lightning arrester, to be co-ordinated with the impulse strength of the special 25-kv class single-bushing transformers suggested by Sumner. This combination would offer an attractive solution to the technical problem, but the activity would have to be reasonably high to produce apparatus which would be economically attractive.

On the basis of the Southside Electric Cooperative tests and our calculations, 15-kv fuses, cutouts and reclosers on a 13.8/23.9-kv system would be exposed to excessive recovery voltages when interruptiug phase-to-phase faults or when interrupting a line-to-neutral fault on one phase during a simultaneous line-to-neutral fault on another phase. Because of these considerations their use is not recommended. We would suggest that a co-ordinated line of fuses, cut-outs, reclosers, switches, and similar devices be considered specifically for 25-kv distribution class multigrounded neutral systems.

We solicit the authors opinions on the maximum future fault current level which will be encountered on these systems, the maximum recovery voltage and the long-term market for apparatus specifically designed for this service.

Wade M. Edmunds and Glenn B. Roloson: Sumner has commented on the probability that the bushings on the transformers installed in 1916 were comparatively small with low-flashover characteristics which would provide relatively good lightning protection at the expense of an abnormal number of fuse outages. Some transformers were installed in 1916, and at various times since, and a large proportion of the total number of transformers were purchased about 1942 and are, therefore, modern transformers with standard size bushings. The statement that the operating experience with the transformers has been excellent does not indicate an abnormal number of outages.

We are pleased that Cunningham's calculations were more in accordance with the tests than the values obtained from the curves in the Westinghouse Electrical Transmission and Distribution Reference Book.

However, there does not seem to be any indication in the book that these curves are not applicable to rural distribution conductor sizes.

Electric Propulsion in Naval Surface Vessels

N. T. JUCARONE
MEMBER AIEE

SHORTLY preceding and during the recent war, the United States Navy constructed or acquired more than 1,100 surface vessels powered with electric propulsion. These vessels included such types as escort vessels, minesweepers, cargo and troop transports, tugs, tenders, tankers, net laying ships, salvage and rescue ships, oilers and oil barges, and ferryboats. The total installed capacity in these ships has exceeded 4,500,000 shaft horsepower.

Although the Navy has been equipping submarines with electric drives for many years, the only electric drives installed in naval surface vessels prior to about 1938 were limited essentially to one collier built in 1913, and to nine capital ships constructed in the decade following World War I. While these early surface installations incorporated the latest features of their period, as described in previous literature,[1,2] the electric propulsion installations in naval service vessels during the World War II period naturally incorporated many improvements as dictated by the most recent design and engineering practices. This paper will therefore be concerned primarily with the recent installations of electric propulsion in naval surface vessels.

It is the author's intention to consider the factors which influenced the use of electric propulsion in naval surface ships, to describe the several types of electric drives employed, and to review some of the major problems associated with these applications. Previous articles,[3,4,5] in recent publications have considered the advantages and disadvantages of electric propulsion and have reviewed applications for merchant and other commercial vessels.

Paper 48-244, recommended by the AIEE marine transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5–7, 1948. Manuscript submitted July 22, 1948; made available for printing August 31, 1948.

N. T. Jucarone is with the Bureau of Ships, Navy Department, Washington, D. C.

Factors Influencing the Use of Electric Propulsion in Naval Surface Vessels

The first electrically propelled naval surface ship, the collier *Jupiter*, which was later converted to the aircraft carrier *Langley*, was equipped with a twin screw a-c turbine electric propulsion plant which was rated about 5,500 shaft horsepower.

This was essentially an experimental installation. The favorable service record of this vessel strongly influenced the choice of a-c turbine-electric propulsion for the seven battleships and the two aircraft carriers constructed shortly after World War I. There were other important considerations, however. Earlier naval ships had been powered with slow-speed prime movers connected directly to the propeller shafts. The desire to employ high-speed steam turbines for propulsion in subsequent naval vessels, because of their low weight and space requirements as compared with slow-speed prime movers, introduced a need for a suitable speed reduction transmission between these high-speed prime movers and the slow-speed propellers. After considering the possibilities of reduction gears and electric propulsion, the latter was selected for these nine capital ships because it allowed greater flexibility in the arrangement of machinery, more economical operation at cruising speeds, and because the development of large reduction gears had not reached the stage where they could be considered reliable for service in naval capital ships.

Subsequent to the construction of these electrically propelled capital ships, however, the turbine geared drive came into extensive use in merchant and passenger vessels and proved itself beyond doubt. Accordingly, when the construction of capital ships was resumed after 1930, the Navy standardized on the turbine geared drive because of the considerable saving in weight and space obtainable by the use of reduction gears in lieu of electric propulsion equipment in plants of high power capacity. Consequently, no further electric drives have been installed in capital ships.

On the other hand, the use of electric propulsion in naval surface vessels requiring propulsion plants of small or medium capacity proved to be more favorable. Prior to World War II electric propulsion had been installed in many commercial vessels equipped with propulsion plants of small or medium capacity and had demonstrated its suitability in these applications. This increasing popularity in commercial applications and considerations of procurement, installation and operation led to the use of electric propulsion in many naval surface vessels requiring plants of corresponding capacity. Some specific considerations which have been of primary importance in the selection of electric propulsion for such naval applications may be noted.

1. Since no rigid mechanical tie is required between the prime movers and the propeller shaft with the electric drive, it permits maximum flexibility in the selection of the number, type, size, and speed of the prime movers, and considerable latitude in the arrangement of machinery. This is of special importance when the prime movers are Diesel engines. During the war, when the available engines were limited to certain types, sizes, and speed ratings, electric propulsion permitted the use of the most readily available types and sizes of engines, and shipboard arrangements best suited to the limited space available.

2. Since electric propulsion provides a means for obtaining speed reduction between prime movers and propeller shafts,

reduction gears may be eliminated. When the availability of reduction gears for propulsion service became critical during the war, electric drives utilizing slow-speed propulsion motors eliminated this bottleneck in the procurement of propulsion plants for many naval vessels, inasmuch as electric propulsion equipment could be procured more readily than large reduction gears. This was an important consideration in the destroyer escort program during the war. In these vessels, both d-c Diesel-electric and a-c turbine-electric propulsion were used, in addition to Diesel geared and turbine geared drives, because of the lack of sufficient gear production capacity to meet the urgent and extensive shipbuilding schedule.

3. The exceptionally favorable operating flexibility of the d-c electric drive at reduced speeds and under towing conditions makes it highly desirable for certain classes of naval surface vessels, such as tugs, ice breakers, salvage ships, and net laying ships.

4. The superior maneuverability of a-c and d-c electric drives as compared with geared or direct drives with fixed pitch propeller, is an important advantage for certain classes of naval vessels.

5. In a vessel equipped with electric propulsion, the propulsion generators may be employed for supplying power to operate large motor-driven auxiliary machinery and for other special purposes, thereby eliminating the need for additional ship's service generating capacity for such requirements. This feature has been used to advantage in minesweepers, tugs equipped with large fire pumps, tenders, tankers, and salvage vessels.

D-C Diesel-Electric Installations

Approximately 750 of the electrically propelled naval surface ships have d-c Diesel-electric drives. While the capacities of these drives range from a few hundred to 13,300 shaft horsepower, the majority are from 800 to 6,000 shaft horsepower. In general, vessels with twin screws have separate and independent plants for each propeller. Each plant contains one to four Diesel-generator sets, one to four propulsion motors, a propulsion control cubicle and the required auxiliaries. The motors are either slow-speed machines, with one double armature or two single armature units in tandem connected directly to the propeller shaft; or high-speed machines, with one to four motors connected to a reduction gear.

A simplified schematic diagram of a plant containing two Diesel-generator sets and two high-speed motors is shown in Figure 1. The generators and motors are connected in a closed ungrounded series loop with the motors and generators alternated so as to avoid the higher potential differences which would exist if the two generators were connected in succession. Each propulsion generator may be connected into or disconnected from the loop, or connected to supply power for special services where desired, by means of a set-up switch. Each set-up switch is provided with a by-pass contact in addition to the contacts for connecting or isolating the generator. The by-pass contact is normally closed when the generator is disconnected, thereby maintaining the continuity of the series loop. When the switch is operated, its opening and closing contacts overlap for a short interval so as to maintain the continuity of the loop while a generator is being connected into or disconnected from the loop. Since the generator armature is short-circuited during this transition, it is necessary to interlock the generator field contactor with the corresponding set-up switch in order to avoid the high circulating currents which would flow if the generator field were energized. With the foregoing arrangement, a generator may be added to or removed from propulsion service without de-energizing any other generators supplying propulsion power.

Disconnect links are provided for each propulsion motor so that it may be disconnected and by-passed in the event of a motor casualty.

Propeller speed is controlled by varying the generator field excitation and engine speed. The direction and magnitude of the generator field current are controlled by means of a potentiometer or similar device, while the engines are maintained at idling speed, which is usually 50 per cent of rated speed. When full generator field excitation is reached, further increase in propeller speed is obtained by increasing the speed of the engines gradually up to rated speed. Engine speed is controlled remotely by means of a mechanical, pneumatic, or electrical linkage which varies the setting of the speed governors on all engines in service simultaneously. The generator field potentiometer and the engine speed control transmitter are mechanically connected to a single handwheel mounted on the front of the propulsion control cubicle, thus permitting control of propeller speed and reversing to be accomplished simply by manipulating the handwheel. Where remote control from the pilot house is desired, a similar speed controller may be provided in a pilot house control stand.

Figure 2 illustrates the manner in which the generator armature voltage, field current, and engine speed vary as the speed controller handwheel is moved to ahead and astern positions. Since the motor armature voltage varies directly as the generator armature voltage, the propeller speed will vary practically in proportion to armature voltage, if the motor field current is maintained constant.

The combination of variable voltage and engine speed control makes it possible to vary the propeller speed smoothly over the entire range from zero to rated speed, either ahead or astern, and to operate continuously even at "creeping" propeller speeds. Also, since the torque developed by d-c motors is determined practically by the product of field flux and armature current, and since the armature current may increase to values of 150 to 200 per cent of rated current while the armature

voltage is at reduced values during starting and reversing, it is possible to obtain peak motor torques equal to 150 to 200 per cent of rated value without overloading the Diesel engines. These desirable features, which are obtainable because of the variable speed transmission ratio and the favorable torque characteristics of d-c motors, make the d-c electric drive superior to the a-c electric drive and to the geared or direct drive with fixed pitch propeller, from the standpoint of maneuverability.

Additional flexibility of control is obtained by the use of a motor field rheostat, which permits varying the speed of the propulsion motors over a predetermined range independently of the voltage and speed adjustments of the Diesel-generator sets. Thus, the motor field rheostat provides a means for varying the speed transmission ratio without varying the generator field excitation. This rheostat is employed primarily for adjusting propeller speed so as to obtain rated output from the Diesel-generator sets in service when any of them are secured or when the propeller load changes because of hull fouling, displacement changes, or other external conditions which vary the ship's resistance to motion. These functions of the rheostat may be explained by reference to Figure 3. Under steady operating conditions the power versus speed characteristic for a fixed pitch propeller is closely approximated by a cubic relation, such as curve 1. When both Diesel-generator sets in a two engine plant are operating at rated output and speed and when the propeller output and speed are also at rated values, operating conditions correspond to point A on curve 1. If one Diesel-generator set is removed from service and no other changes are made, the motor armature voltage is reduced to 50 per cent of its rated value and hence the propeller speed drops to 50 per cent of rated speed. Under this condition the propeller output, as determined by point B on curve 1, is only 12.5 per cent of rated power, and the output of the Diesel-generator set in service is reduced to only 25 per cent of its rated capacity, although the set is still operating at rated speed. By means of the motor field rheostat, however, the propeller speed may be increased until the propeller output is 50 per cent of rated shaft output, as indicated by point C on curve 1. At this new propeller speed, which is 79.4 per cent of rated value, the Diesel-generator set in service will be delivering its rated capacity at rated speed. Hence, in the two engine plant, a range of at least 29.4 per cent speed increase by motor field control is required to obtain rated engine output when one set is secured.

Likewise, when external conditions increase the ship's resistance, more power is required to turn the propeller at a given speed. Hence curve 1 assumes a new position, such as shown by curve 1′. The position of this second curve is not intended to be quantitative, since this depends upon how much the ship's resistance increases. Under the new operating conditions, the propeller output at rated speed would exceed rated value, as indicated by point D on curve 1′, and the two Diesel-generator sets would be seriously overloaded. By means of the motor field rheostat, however, the propeller speed may be reduced until the propeller output is restored to rated value, as indicated on point E on curve 1′, and the Diesel-generator sets are delivering rated capacity at rated speed. The load on fixed pitch propellers designed for towing service usually is maximum when the vessel is stationary and becomes equal to rated power at about 75 per cent of rated propeller speed. Hence, in such applications, a range as high as 25 per cent speed reduction by motor field control is very desirable in order to utilize the full output of the plant under maximum tow conditions.

For the two engine plant considered in the foregoing example, a total range of speed variation by motor field control equal to at least 55 per cent of rated speed would be required in order to obtain the desired flexibility of control in vessels in which towing is a primary function.

The electric protective devices shown in Figure 1 consist of a short-circuit relay and a current-limiting relay, both of which have their operating coils connected in the propulsion-loop circuit. The short-circuit relay operates at 250 to 300 per cent of rated loop current and when actuated, trips the motor and generator main field contactor, thereby de-energizing the propulsion loop in the event of excessive current. This relay resets automatically and the operator may restore excitation simply by returning the speed controller to the "off" position in the event that tripping of the relay was caused by peak currents of short duration. The current limiting relay operates at lower values of loop current, usually 110 to 125 per cent of rated value; its function being to limit the peak currents and the rate of current rise during maneuvering, turning, and rapid reversals. When actuated, this relay inserts additional resistance in the excitation circuit of the propulsion generators. The resistance is retained in the excitation circuit until the loop current returns to rated value.

Propulsion excitation and control power is obtained from any reliable 120- or 240-volt d-c source, which may be the ship's service d-c system, motor-generator sets, or exciters directly connected to or belt-driven by the propulsion Diesel-generator sets. Separate exciters may be provided for the propulsion motors and generators, with control effected by regulating the field current of these exciters.

A typical propulsion control cubicle used in harbor tugs is shown in Figure 4. In this instance a single multiposition set-up switch, actuated by the left handwheel, was provided for the two propulsion generators. The handwheel-operated main speed controller is shown in the

center, with motor field rheostats located directly above. The two voltage regulators at the right are required for maintaining the voltage of the two direct-connected propulsion exciters constant throughout the engine operating speed range. The four circuit breakers below the regulators are for connecting either exciter to supply propulsion excitation and control power or auxiliary ship's service power. The propulsion cables enter from below.

D-C Propulsion Motors and Generators

These are heavy-duty marine-type class-B insulated, separately-excited shunt machines. Propulsion generator capacities range from 150 to 1,375 kw, at rated speeds of 600 to 900 rpm. Propulsion motor capacities range from 200 to 5,000 hp, at rated speeds of 100 to 600 rpm for direct-connected motors and 700 to 1,500 rpm for geared motors. Armature voltages are maintained under 1,000 volts so as to minimize personnel hazards and insulation problems. Some features of interest in naval applications will be considered in the following paragraphs.

In applications where towing duty is important, the propulsion motors are designed for rated capacity over a speed range of about 25 per cent in order to match the propeller load requirements under maximum towing conditions.

When engine capacities are below about 1,000 brake horsepower, each propulsion generator usually is provided with a series field for starting the Diesel-generator set electrically from a storage battery.

The machines are constructed as light in weight and as compactly as practicable without sacrificing reliability and ruggedness. In order to minimize damage from shock, Navy specifications require steel construction, body-bound coupling and foundation bolts, and locking devices to prevent brushes from becoming dislodged. Cast iron and other materials of low impact strength are not acceptable.

Pressure-lubricated or self-lubricated sleeve-type bearings are preferred because of the greater reliability and easier maintenance of such bearings in machines of large capacity, as compared with ball or roller bearings. The same type of lubricating oil is used for motor and generator pressure-lubricated bearings as is required for the Diesel engines.

Careful attention is given to the arrangement of terminal connections and to the wiring around the frame in order to minimize the external magnetic fields which would be produced by unbalanced ampere turns around the motor or generator shaft, since such magnetic fields cannot be completely neutralized with degaussing coils and may be of sufficient magnitude to create a hazard in mined waters. External fields have been eliminated so effectively that even minesweepers have been equipped with d-c propulsion machines with complete confidence.

Experience has shown that electric strip heaters installed in each propulsion motor and generator are very desirable as a means of maintaining insulation dry when the machines are secured, particularly in tropical climates.

The problem of providing adequate ventilation for the propulsion motors and generators has required considerable attention. In the majority of machines of 1,000 hp or 1,000 kw capacity, ventilating air is drawn from the machinery spaces and is circulated through the machines by fans attached to the rotors or separately motor-driven. When the heated air from these machines is exhausted into the machinery spaces, an excessive rise in ambient temperature results and a considerable amount of the heated exhaust air is recirculated into the machines, unless an elaborate machinery space ventilating system is provided and barriers to prevent recirculation are installed. These undesirable conditions were aggravated by the necessity of operating in tropical climates during wartime with hatches and openings to the weather secured. In order to overcome these undesirable conditions, the use of ductwork attached directly to the exhaust outlets of the motors and generators and discharging the exhaust air outboard, was resorted to in many vessels. However, while this arrangement overcame the difficulties noted, it introduced a new problem, since the machines became exposed to damage from water entering or condensing inside the ductwork and subsequently entering the machines. As a consequence, the Navy eventually resorted to the use of enclosed machines with water-to-air heat exchangers, for propulsion motors and generators of all capacities. These self-contained water-cooled machines have proved very satisfactory in overcoming the problems of ventilation. In addition, the completely-enclosed construction makes it easier to protect the machines from water damage and from the oil and dirt always present in the machinery spaces.

Figure 5 is a sectional view of a large d-c propulsion generator, showing the double-tube type cooler, sleeve type pressure-lubricated bearings, and the fan attached to the rotor. The frame and armature spider are constructed of fabricated steel to reduce weight. The casing below the frame feet is watertight to protect against flooding when the water level in the bilges rises.

A-C Diesel-Electric Installations

Only two naval vessels have been equipped with a-c Diesel electric propulsion. The total capacity installed in the first vessel, a twin screw catapult lighter, was 1,100 shaft horsepower. Since this vessel was never actually placed in service it will not be considered further in this paper. The second naval vessel with this type of drive is the submarine tender *USS Sperry*. This twin screw, 10,000 ton

ship which was completed in 1942, is of considerable interest since, it is the first naval ship and the largest commercial or naval vessel equipped with a-c Diesel-electric propulsion ever placed in operation in the United States. Consequently this tender has served as a trial ship for demonstrating and evaluating the a-c Diesel-electric drive. The highly successful trials and creditable performance of the *Sperry* have substantiated the Navy's interest in this type of drive. Further installations were being considered for additional submarine tenders, but termination of hostilities interrupted the construction program.

The *Sperry* has two separate and independent propulsion plants, one for each propeller. Each plant is rated 5,900 shaft horsepower, and contains four Diesel-generator sets and one slow-speed synchronous propulsion motor. A simplified schematic diagram of the plant for one shaft is shown in Figure 6. The synchronous generators may be connected in parallel in any combination from one to four, depending upon power requirements. Since the generators have salient poles with damper windings in the pole faces, any unit can be connected to the bus simply by bringing it up to approximately synchronous speed, closing its circuit breaker and energizing its field. Synchronizing instruments are not required. In fact, it was found possible during the trials of this vessel to start a Diesel-generator set from rest by motorizing its generator from the propulsion bus. Any propulsion generator may be readily added to or removed from the bus without removing power from the propeller.

Since each propulsion motor also has salient poles and a damper winding, it can be started as an induction motor and synchronized when up to approximately synchronous speed. Reversing is accomplished by reversing two of the phase leads to the motor. Prior to reversing, the motor is slowed down rapidly by dynamic braking. After the motor has been reversed and accelerated in the reverse direction up to approximately synchronous speed, it is again synchronized. During the trials of the *Sperry* the period of dynamic braking and the amount of braking resistance were varied until optimum conditions for most rapid propeller reversals without stalling the engines were realized. After these adjustments had been made, successful reversals were accomplished with only two engines in service per shaft.

Propeller speed is controlled by varying the speed of the Diesel-generator sets in service simultaneously over a speed range from 30 per cent to rated engine speed, thereby varying the frequency and the motor speed proportionally. During starting and reversing, the Diesel-generator sets are maintained at the idling speed of 30 per cent rated speed until the motor is synchronized, and strong over-excitation is applied to the propulsion generators. Strong over-excitation is applied also to the propulsion motor during the synchronizing period so as to obtain maximum pull-in torque. Control of engine speed, field excitation, and of the motor and generator circuit breakers is accomplished by means of operating levers located at the front of the propulsion-control cubicle. A more detailed description of the a-c Diesel-electric propulsion control system has been ably presented in an earlier paper.[6]

Because of the fixed speed transmission ratio between the engines and the synchronous motor in each plant, and in view of the less favorable torque characteristics of a-c machines as compared with d-c machines, the operating characteristics of the a-c Diesel-electric drive are not quite as favorable as for the d-c Diesel-electric drive. With the a-c drive, the propeller cannot be operated continuously at speeds below 30 per cent of rated speed without the addition of special equip-

Figure 7. Relation of shaft power to propeller and engine speed in a four engine a-c Diesel electric plant

ment, and the maximum motor torque which can be developed during starting and reversing is limited to not more than about 110 per cent of rated torque. On the *Sperry* it was found necessary to install a torque regulator in each plant in order to limit the maximum output of the engines during induction motor operation, when starting and reversing. This regulator functions to insert resistance in the field excitation circuit of the propulsion generators when the engine speed is reduced below a predetermined value because of insufficient engine torque.

The a-c Diesel-electric drive is limited also with respect to the maximum power obtainable when one or more of the engines are secured and when the propeller load changes because of a change in external conditions. Referring to Figure 7, when four Diesel-generator sets are operating at rated capacity and rated engine speed, steady operation under rated conditions corresponds to point A on curve 1. If the engines are capable of operating at rated mean effective pressure over their operating speed range, the maximum output of each engine will be proportional to engine speed. Hence, the maximum shaft power with one, two, three and four engines in service per shaft may be represented by the four straight lines in Figure 7 which intersect the 100 per cent speed ordinate at 25, 50, 75 and 100 per cent shaft power, respectively. If one Diesel-generator set should be removed from service without changing the speed of the three sets remaining in service, these sets would be seriously overloaded, since the three engines would be required to deliver rated shaft power, or 133 per cent of rated engine capacity per engine, as long as the propeller operated at rated speed. To avoid overloading the engines in service their speed must be reduced until operation corresponds to point B on curve 1, which is the intersection of curve 1 and the curve for maximum output with three engines in service. At point B the shaft power is 65 per cent of rated value and the output from each engine in service is 86.7 per cent of rated engine capacity. This is the maximum shaft power and engine output which can be obtained when three Diesel-generator sets are in service without overloading them. Similarly, the shaft power when only two and one Diesel-generator sets are in service is determined by points C and D, respectively. The maximum engine outputs corresponding to points C and D are 70.7 and 50.0 per cent of rated engine capacity, respectively. Thus, in contrast to the d-c electric drive, in which rated output can be obtained from the prime movers irrespective of the number of units in service, with the a-c Diesel-electric drive it is necessary to operate at less than rated engine capacity when any of the sets are secured.

Likewise, when external conditions cause the propeller load to increase, as represented by curve 1′ in Figure 7, it is also necessary to reduce the speed of the Diesel-generator sets in service, and consequently the propeller speed, in order not to overload the engines. The maximum engine output and shaft power under the new conditions when four diesel generator sets are in service per shaft are determined by point A′ on curve 1′. As in the previous case, the maximum engine output is less in the a-c Diesel-electric drive than in the d-c electric drive, because of the necessity of reducing the speed of the Diesel-generator sets in the former drive when external conditions cause the propeller load to increase.

It should be noted that the foregoing limitations apply not only to the a-c Diesel-electric drive, but also to the Diesel geared and direct drives with fixed pitch propellers, since the speed transmission ratio is fixed in these drives also. However, in the majority of naval surface vessels with propelling plants of medium or higher capacity and in which the a-c Diesel-electric drive appears to be more promising because of its higher over-all efficiency at rated output, greater reliability and lower weight as compared with the d-c Diesel-electric drive, the above limitations are usually not too serious. In such vessels, a high degree of maneuverability and superior towing characteristics are in general not primary considerations.

The electric protective devices consist of a phase-balance relay and a ground relay. The former provides protection in the event of a severe unbalance in phase voltages, by de-energizing the field circuits of the propulsion motor and generator exciters. The latter relay is energized when a ground occurs, causing an alarm to sound and an indicating light to flicker. Since the propulsion circuits are not grounded, it is not essential to de-energize the system immediately in the event of a single ground.

The propulsion plants in the *Sperry* are designed to utilize propulsion generators for supplying other ship power requirements as well as propulsion power. Any of the propulsion generators in the port shaft plant can be utilized to supply an 850 kw, a-c/d-c motor-generator set which is used for charging submarine storage batteries; and two of the propulsion generators in either the port or starboard shaft plant can be utilized to supply 450-volt a-c 60-cycle power for large arc furnaces and for other services, through a suitable transformer.

Power for propulsion excitation and control requirements is obtained from three motor-generator sets, one being provided for each plant and the third being a standby unit for either plant. Each set consists of an a-c motor, a propulsion motor exciter, a propulsion generator exciter and a control power generator. Excitation and control circuits are 120 volts, direct current. During starting and reversing, generator field over-excitation is obtained by connecting the motor and generator exciters in series to supply 240 volts.

Figure 8 shows one of the two propulsion control cubicles installed in the *Sperry*. The high-voltage circuit breakers and instrument transformers are located

in the rear section and the low-voltage equipment is located in the front section; the two sections being separated by a passageway at the center and entered through the door. The dynamic braking resistors are shown at the top center of the cubicle. The operating desk contains four levers for controlling each of the four propulsion generator line circuit breakers and field contactors; one lever for controlling the propulsion motor starting, reversing and dynamic braking circuit breakers and the motor field contactors; one lever for controlling the 850-kw motor-generator set line circuit breaker; and one lever for regulating the engine speed master transmitter and motor and generator field excitation. The handwheel to the right controls the exciter selector switch.

A-C Propulsion Motors and Generators

These are heavy-duty marine-type class-B insulated 3-phase salient-pole synchronous machines, with damper windings in the pole faces. Each of the eight propulsion generators is rated 1,150 kva, unity power factor, 2,400 volts, alternating current, 750 rpm. Each of the two propulsion motors is rated at 5,900 horsepower, 2,400 volts, alternating current, 139 rpm. Operating frequencies range from 18.7 cycles per second at idling speed to 62.5 cycles per second at rated engine speed. The machines are completely enclosed and are equipped with water-to-air heat exchangers of double tube construction. The generators have ventilating fans attached to the rotors and the motors are provided with motor-driven blowers. The same considerations for obtaining light weight, compactness, resistance to shock and reliability govern in the construction of these a-c machines as were discussed in the case of d-c propulsion machines.

Figure 9 is a view of the coupling end of one of the eight propulsion generators installed in the *Sperry*. Two fans, one attached to each end of the rotor, circulate the ventilating air radially through the stator and through the cooler located on top of the frame. The terminals, shown exposed, are taped and enclosed in a drip-proof terminal box when installed. The pressure-lubricated sleeve bearings are supported directly on the end bells. This is preferred to the usual pedestal-type bearing because of the reduction in over-all length and the reduced possibility of the rotor shifting with respect to the stator.

A-C Turbine-Electric Installations

Approximately 350 of the electrically propelled naval surface vessels have been equipped with a-c turbine-electric drives. While the capacities of these range from 2,500 to 20,000 shaft horsepower in the recent applications, the majority are from 3,300 to 12,000 shaft horsepower. All of the installations made during the World War II period have a separate plant for each propeller; each plant consisting of a single turbine-generator set and a slow-speed propulsion motor. Single units are used in preference to multiple units because of the reduced weight per horsepower and higher efficiencies obtainable with turbines, generators, and motors of increased capacity; and in view of the high degree of reliability of steam turbines and a-c machines. While each plant in a twin screw vessel is entirely self-contained and may be controlled independently of the other plant, either propulsion generator may be connected to supply the two propulsion motors simultaneously. This added flexibility permits operating at reduced speeds with only one turbine-generator set in use, thus improving the operating efficiency at reduced speed and providing an opportunity for inspecting and servicing the secured set while underway.

A simplified schematic diagram of a plant having one turbine-generator set and one motor is shown in Figure 10. The electric power and control system is similar to that described for the a-c Diesel-electric drive except for the simplifications introduced by the use of only one generator and motor per plant, and differences to be noted in the following. In most turbine-electric drives dynamic braking is not required since the high inherent torque capacity of steam turbines at reduced speeds practically eliminates the possibility of stalling them during rapid reversals. Dynamic braking was found necessary in only one class of vessels, which consisted of seven troop transports, each having two propellers and two 10,000 shaft horsepower propulsion plants. In this instance, rapid reversals conducted before dynamic braking was provided causing the damper windings in the propulsion motors to overheat and their brazed connections to loosen. The installation of dynamic braking resistors remedied this difficulty. This application proved to be a good example of the importance of carefully correlating the ship and propeller characteristics with the capacity and design characteristics of the a-c propulsion system.

The line contactors are interlocked with the field contactors so that the line contactors cannot be operated while the field excitation circuits are energized. Consequently, the line contactors need be designed to interrupt only a fraction of rated power.

As in the a-c Diesel-electric drive, propeller speed is controlled by varying the speed of the turbine-generator set. However, a greater range of speed variation is obtained since the turbine speed is varied from rated to as low as 15 per cent of rated speed.

When steam turbines are employed as prime movers, stability requirements influence the design of the a-c propulsion system to a greater degree than when the prime movers are Diesel engines. In the a-c Diesel-electric drive, momentary increments in propeller torque, such as are caused by rolling, pitching and turning, are reflected in momentary reduction in the speed of the Diesel engines because of

the relatively low inertia of the rotating masses and the lag in response of the speed control system. The reduction in propeller speed which results is effective in limiting the magnitude of such torque increments. In addition, Diesel engines are usually provided with mean effective pressure limiters which reduce the engine speed, irrespective of the governor setting, when engine torque exceeds rated torque by 10 to 15 per cent. Hence, in a-c Diesel-electric drives, propulsion motors and generators designed with a torque margin of only 10 to 15 per cent more than rated torque at normal excitation, will usually be adequate to insure stability when the propeller torque varies momentarily. When the prime movers are steam turbines, however, the inertia of the rotating masses is relatively high, and consequently momentary increments in propeller torque are transmitted through the propulsion motor and generator to the turbine without any perceptible reduction in the speed of the system. Hence, in a-c turbine-electric drives, the a-c propulsion system must be designed to absorb higher momentary torque increments than in a-c Diesel-electric drives. In order to avoid the use of oversize propulsion motors and generators, the usual practice is to provide a fast acting regulator, such as an amplidyne or a Rototrol, in the control system of a-c turbine-electric drives. The regulator is usually connected to regulate motor and generator field excitation automatically so as to maintain the ratio of generator voltage to frequency essentially constant and the system power factor at unity throughout the operating speed range. Momentary increments in propeller torque cause the regulator to increase the amount of motor and generator field excitation correspondingly, and hence the torque margin of the machines is raised momentarily a sufficient amount to insure stability. By the use of such regulators, in conjunction with turbine steam flow regulators which limit the maximum turbine overload, motors and generators may be designed with a torque margin as low as only 5 per cent of rated torque.

Because of the fixed speed transmission ratio between the turbine-generator set and the propulsion motor, the maximum sustained output which the plant can deliver when external conditions change is limited in the same manner as in the a-c Diesel-electric drive. However, the limitation in maximum sustained output is usually determined by the propulsion motor and generator rather than by the capacity of the steam turbine. If the capacity of the turbine-generator set, as determined by the maximum permissible output of the generator, is assumed to vary linearly with speed throughout the operating speed range, then the curve for four engine maximum output in Figure 7 may be taken also as the maximum output curve of the turbine-generator set. Hence, if external conditions cause the propeller characteristic to be displaced from curve 1 to curve 1′ in Figure 7, then the speed of the turbine-generator set and of the propeller must be reduced until operating conditions correspond to point A′ on curve 1′, as in the case of the a-c Diesel-electric drive. Since only one turbine-generator set is provided in each plant, the limitations relative to the use of multiple prime movers per shaft considered previously for Diesel-electric drives do not apply. However, when one turbine generator set is used to supply both propulsion motors in a twin screw vessel, the maximum operating speed and output of the turbine-generator set in service must be limited in the same manner as when only two engines in a four engine a-c Diesel-electric plant are in service. Thus, when one turbine generator set is supplying power to both propulsion motors, maximum operating conditions will correspond to point C on curve 1 in Figure 7, when the ship's resistance is normal. At this point, the output from the turbine-generator set in service is 70.7 per cent of rated capacity, and each propeller is operating at 70.7 per cent of rated speed and absorbing 35.4 per cent of rated shaft power.

When steam turbines are used as prime movers, the advantages of using a-c machines in preference to d-c machines are so favorable that only a-c machines have been employed in turbine powered naval surface ships with electric drives. This is attributable primarily to the considerable savings in weight and space possible when high-voltage high-speed a-c generators are used in lieu of inherently low-voltage medium-speed d-c generators.

Figure 11 shows a propulsion control cubicle installed on the upper level in the machinery spaces of a turbine-electric surface vessel. The operating desk contains one motor set-up lever, one motor reverser lever, one field lever, one turbine governor speed control lever and one emergency turbine throttle control lever. The handwheel to the right is for turbine load limit control. Meters are Navy approved high-impact instruments.

A-C Propulsion Motors and Generators

These are similar in construction to the a-c machines described for the a-c Diesel-electric drive with the principal exception that the propulsion generators are cylindrical-rotor high-speed machines. The capacities of propulsion generators range from 2,000 to 7,650 kw, at rated speeds of 3,000 to 5,600 rpm. Capacities of propulsion motors range from 2,500 to 10,000 hp at rated speeds of 90 to 400 rpm. Rated a-c voltages range from 2,000 to 3,600 volts. Operating frequencies range from 50 to 93 cycles per second at rated speed.

In numerous installations, heat exchangers of single tube construction have been provided for the a-c propulsion motors and generators. Several serious casualties have occurred when leaks developed in the tubes of the coolers and resulted in salt water damaging stator and rotor insulation. The Navy's experience has fully justified its preference for coolers of double tube construction as a protection against such hazards.

Synchronous motors with damper windings in the pole faces are used exclusively in preference to induction motors in all recent naval applications because of the relatively lighter weight, higher efficiency and higher power factor obtainable with synchronous motors.

Figure 12 shows an assembly view of a complete propulsion turbine-generator set, and views of the generator stator winding and cylindrical rotor. The compactness and light weight but rugged construction are apparent. The rotor is supported on a single bearing at the free end and is connected by a forged-on flange directly to the turbine shaft.

Figure 13 shows several views of an a-c propulsion motor. The collector rings are located outside the motor enclosure for accessibility to brushes and collectors. Self-lubricated disk-type sleeve bearings are employed. The sturdy damper winding construction is apparent. In this application, the motor speed was sufficiently high to permit the use of fan blades attached to the rotor, in lieu of separate motor-driven fans as is more frequently the case.

Comparison of A-C and D-C Diesel-Electric Drives in Submarine Tenders

It is of interest to compare the a-c Diesel-electric installation in the submarine tender *Sperry* with the d-c Diesel-electric installations of comparable capacity in the six submarine tenders designated as *AS11*, *AS15* to *AS19*, inclusive. Each of these tenders has two propellers and propelling plants rated approximately 6,000 shaft horsepower per shaft. The prime movers in each vessel consist of eight General Motors model *16-278A* Diesel engines (four per shaft). Hence, these tenders provide an opportunity for comparing a-c and d-c electric propulsion systems in plants which are essentially similar with respect to application, capacity, prime movers, and installation features.

A summary of the weights of the major electric components in these plants is given in Table I. Although these weights

Table I. Weights of Electric Propulsion Equipment in Diesel-Electric Submarine Tenders

Electric Components	AS12—A-C Drives 11,800 Total Shaft Horsepower		AS13–19—D-C Drives 11,200 Total Shaft Horsepower	
	Rating	Number × Weight, Pounds	Rating	Number × Weight, Pounds
Propulsion motors	5,900 hp, 139 rpm	2×61,400	1,440 hp, 750 rpm	8×16,900
Reduction gears			5.64:1 ratio	2×55,500
Propulsion generators	1,150 kw, 750 rpm	8×10,300	1,125 kw, 750 rpm	8×16,900
Propulsion control cubicles		2×23,000		2×6,100
Propulsion M-G sets and controllers	180 hp/114.5 kw	3×11,500	60 hp/40 kw	4×3,800
Total weight, pounds		285,700		408,800
Pounds per shaft horsepower		24.2		36.5

Table II. Efficiencies of Electric Propulsion Equipment in Diesel-Electric Submarine Tenders

Vessels	Drive	Component Efficiencies: Propulsion Generators	Propulsion Motors	Reduction Gear	Over-all Transmission Efficiency
AS 12	A-C	97.8	97.0		94.9
AS15–19	D-C	95.2	95.2	98.0	88.7

Note: Efficiencies are based on rated output and are calculated from factory test data. Motor and generator excitation losses and power requirements for associated auxiliaries are not included.

are approximate, being based on manufacturers' design calculations, and do not include the weights of cable and auxiliaries, they are sufficiently accurate to indicate the considerable savings in weight realized with the a-c drive. Thus, the weight of the d-c electric equipment is approximately 1.5 times that of the a-c electric equipment. It should be noted that in the d-c drives, since high-speed d-c propulsion motors coupled to reduction gears are employed, the weight of the gears have been included also. If slow-speed motors had been employed, the weight of the d-c electric equipment would have been appreciably higher. The relatively higher weight of the a-c propulsion control cubicles, as compared with the d-c cubicles, is attributable primarily to the use of more elaborate control equipment and magnetically operated circuit breakers in lieu of manually operated circuit breakers or contactors. With the experience gained from this first installation, it is believed that in future a-c Diesel-electric drives, appreciable reduction in the weight of the control equipment, and hence reduction in the weight of the a-c electric equipment per shaft horsepower, should be possible.

The size of the propulsion rotating machinery is frequently of paramount importance because of the limited space available on the lower level in the machinery spaces. The space required for the a-c propulsion motors and generators is appreciably less than that required for the d-c motors, generators and reduction gears, in these tenders. On the other hand, the a-c control cubicles are almost twice as large as the d-c cubicles. However, as noted previously, future simplifications and refinements should result in relatively smaller a-c cubicles.

A summary of the component and over-all transmission efficiencies from the prime movers to the propeller shafts is shown in Table II. The higher over-all efficiency of the a-c drive is reflected in a slightly higher shaft output at rated capacity as compared with the d-c drive, even though the total prime mover capacity is the same for both drives. It should be noted, however, that at speeds and outputs appreciably below rated value the fuel consumption per shaft horsepower is probably somewhat lower for the d-c drives than for the a-c drive, since in the former the Diesel-generator sets in service can be operated at speeds corresponding to optimum output because of the variable speed transmission ratio obtainable with the d-c drives.

As has been expected, the a-c electric propulsion equipment in the *Sperry* has required less servicing than the corresponding d-c equipment in the remaining tenders. Some unanticipated difficulties have been experienced with both types of drives. In the a-c drive, on several occasions the interconnections between the field coils of the a-c propulsion motors loosened. This was remedied by resoldering the connections more carefully with silver solder. Breakage of fan vanes in the a-c propulsion generators also occurred and was corrected by bracing the vanes. In the d-c drives, the rotor fans in the propulsion motors and generators developed cracks in the fan blades. All of these fans are being replaced with fans of more rugged construction. The d-c machines have required more frequent cleaning and servicing than the a-c machines because of the accumulation of carbon and copper particles, in conjunction with oil and moisture, on the uninsulated surfaces in the d-c machines. In several instances, partial flooding of the d-c motors and generators has necessitated extensive overhauls and replacement of armatures and field coils. On the other hand, no major overhauls of the a-c machines in the *Sperry* have been required to date.

The foregoing comparison furnishes convincing support for the use of a-c electric propulsion equipment in Diesel-electric drives where plants of medium or higher capacity are required, and where the attainment of maximum flexibility and maneuverability is not of primary importance. A-c Diesel-electric propulsion should accordingly find many applications in plants having capacities of about 3,000 shaft horsepower per shaft and higher.

Status of Electric Propulsion in Naval Surface Vessel Applications

Based upon experience acquired with naval surface vessels constructed and operated during the recent war, considerable progress has been made in establishing the basic requirements essential in the

Table III. Summary of the Fields of Application of the Three Conventional Electric Drives in Naval Surface Vessels

	D-C Diesel Electric Drive	A-C Diesel Electric Drive	A-C Turbine Electric Drive
Most probable capacities	Up to about 3,000 shaft horsepower per shaft*	3,000 to 12,000 shaft horsepower per shaft**	Above about 3,000 shaft horsepower per shaft
Primary reasons for use	1. Optimum maneuverability	1. Adaptability with multiple Diesel engines per shaft	1. Availability of propulsion generators for supplying a-c auxiliary power
	2. Optimum operating flexibility	2. Availability of propulsion generators for supplying a-c auxiliary power	2. Superior maneuverability over turbine geared drives
	3. Adaptability with multiple Diesel engines per shaft	3. Superior maneuverability over Diesel geared or direct drives	3. Greater over-all efficiency at cruising speeds and better operating flexibility than turbine geared drives in twin screw vessels
	4. Availability of propulsion generators for supplying d-c auxiliary power	4. Greater reliability, less maintenance and lower space and weight requirements than d-c Diesel-electric driven	4. Higher capacity range than plants with Diesel engine prime movers
Most probable naval surface vessel applications	Ice breakers (AG), minesweepers (AM), net laying ships (AN), salvage ships (ARS), rescue ships (ASR), gasoline tankers (AOG), ocean tugs (ATA, ATF), harbor tugs (YTB, YTM, YTL), fuel oil barges (YO), ferry boats	Destroyer escorts (DE), submarine tenders (AS)	Destroyer escorts (DE), cargo and troop transports (AP, APD, APA, AKA), oilers (AO)

* An exception to this limit is the use of d-c Diesel-electric propulsion in ice breakers, which require capacities as high as 5,000 shaft horsepower per shaft.

** The upper capacity limit for a-c Diesel-electric plants is based upon the use of not more than five engines per shaft, and engine capacities not exceeding about 2,400 brake horsepower.

construction and installation of electric propulsion equipment for naval service in order to insure a high degree of reliability and good performance without requiring excessive maintenance or attention. Because of the urgency of wartime requirements and the lack of basic naval specifications, most of the electric propulsion equipment provided for the earlier applications was essentially of commercial design. However, improvements in design, installation and operating practices were effected in later installations. Naval basic specifications[7,8] covering the construction and installation of electric propulsion equipment are now available and will be revised periodically as additional experience is acquired. Accordingly, the Navy is more adequately prepared for future applications of electric propulsion in naval surface vessels than in the past. However, it is expected that future applications will be determined primarily by engineering and performance considerations, particularly during peacetime, rather than by procurement considerations, as was frequently the case during the recent war. Based upon engineering and performance considerations, the most probable fields of application of the three types of conventional electric drives in naval surface vessels may be summarized as in Table III.

It should be noted, however, that electric propulsion must compete with other developments in the field of marine propulsion, such as the development of reliable controllable and reversible pitch propellers, improved types of reversible reduction gears and clutches, and lightweight planetary gears. Consequently, it is important that the development of electric propulsion equipment toward obtaining more reliable, lighter and more compact equipment be continued. Along these lines, the further simplification and development of control equipment to withstand high impact shock, the incorporation of space and weight saving materials and construction features, and the use of high-temperature insulating materials, such as those utilizing silicone varnishes and impregnants, are important. If interest in electric propulsion is to be maintained in the face of developments in other fields, it is essential that the further development of electric propulsion equipment be carried out during peacetime, despite the relatively small present naval demand for such equipment.

Some of the more recent developments which should serve as incentives toward extending the use of electric propulsion in naval surface vessels may be noted.

1. Development of gas turbines for marine propulsion. Since gas turbines are essentially high-speed, undirectional, non-self-starting prime movers, and must be operated at constant speed or over a limited speed range for efficient service, they require a transmission system which will provide speed reduction and overcome the deficiencies of gas turbines for propulsion service. Electric propulsion is probably the most promising transmission system available at present for this purpose. In this connection, d-c electric drives have inherently the best operating characteristics for use with gas turbines because of the variable speed transmission ratio obtainable with d-c machines. On the other hand, because of the high prime mover speeds and the higher capacities in which gas turbines appear most promising, a-c electric drives permit considerable reduction in weight and space, as well as increased reliability, as compared with d-c electric drives.

In order to overcome the fixed speed transmission ratio inherent in a-c synchronous electric drives and thereby make them more adaptable for use with gas turbines, the Bureau of Ships and several manufacturers are developing an a-c electronic propulsion system which appears to offer promising possibilities. In the a-c electronic system synchronous machines of essentially conventional design are employed. However, the a-c power from the generators is supplied to a cyclo-converter, which is essentially a frequency changer. The cyclo-converter contains 18 sealed mercury pool-type power tubes. By control of the supply to the grids and igniters of these tubes, it is possible to vary the frequency of the a-c power output from the cyclo-converter continuously over the entire operating range, independently of the input power frequency. In addition, the phase sequence of the output power can be reversed. The electronic propulsion system therefore should provide the same variable speed transmission ratio as can be obtained with d-c electric propulsion, while still retaining the advantages inherent in the use of a-c machines. It is anticipated that a detailed description of this system and of its performance will be published at some future date.

2. Trend toward higher speed steam turbines and other high-speed prime movers. Prime mover speeds well in excess of 5,000 rpm may be expected in the future. The greater speed reduction required with these prime movers will probably necessitate the use of gears with three stages of speed reduction when geared drives are used. The increased size and weight of such gears may be such as to at least partially cancel the present weight and space superiority of geared drives over electric drives of comparable capacity in such applications.

3. Increased importance of reducing the noise level of the propelling plant to a minimum in certain classes of naval vessels. The principal sources of noise are the propellers and reduction gears. Propeller noise can be minimized by careful attention to propeller design and by using lower speed propellers. However, lower speed propellers necessitate the use of reduction gears with higher gear ratios, which in turn increases the noise level of the gears. While considerable work is being carried on in an attempt to develop more quiet reduction gears, nevertheless the inherent quietness of the electric drive utilizing slow-speed propulsion motors makes this drive very attractive where extreme quietness of operation is desired.

4. Trend toward ever increasing capacities of propelling plants for certain types of naval vessels. With increased plant capacities, the problems connected with the arrangement of machinery become increasingly difficult. Also, the number, weight, and length of propeller shafts increase. Considerations of vulnerability and weight and space requirements for shafting may lead to reconsideration of electric propulsion in naval vessels with propelling plants of large capacity, since the propulsion motors may be placed well aft in the ship, thereby reducing the length and size of the shafting.

Conclusions

It is hoped that the preceding discussion has served to acquaint the reader with the background and present status of electric propulsion in the United States Navy, and that it will stimulate further interest in this field. Space limitations and other considerations have prevented the inclusion in this paper of detailed data relative to the performance of the several types of electric drives, particularly as compared with other types of drives. However, it is anticipated that additional publications will be released to supplement this article so that equipment manufacturers and ship operators may benefit from the Navy's experience with electric propulsion in naval surface vessels.

Discussion

H. C. Coleman (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The United States Navy pioneered in furthering the development and application of electric propulsion equipment for ships. This participation in and encouragement of such application has been of benefit in adopting this form of drive to many types of merchant vessels. In view of the outstanding interest and experience of the Navy in electric propulsion, it is not surprising to find that there were more than 1,100 surface vessels equipped with electric propulsion in the last ten years. This paper gives an interesting and valuable summary of the various types of drives applied on these vessels.

The description of the a-c Diesel-electric drive on the submarine tender *Sperry* is a good example of the Navy's pioneering. The experience gained on this installation should lead the way to the utilization of this type of drive on certain large merchant vessels.

The author indicates that with the drive such as used on the *Sperry* the propeller cannot be operated continuously at speeds below 30 per cent of rated speed without the addition of special equipment. This is true, but special equipment is rather simple. It is possible to operate the synchronous motor as a squirrel-cage induction motor by proper adjustment of the generator excitation below its normal value and with the motor field connected to a resistor. Thus, very little extra equipment is involved.

The author states that the maximum motor torque which can be developed during starting and reversing is limited to not more than about 110 per cent of rated torque. Actually, such a high torque is not realized. Under the maneuvering condition the engine speed is reduced to about 30 per cent, and at this speed the engine will not produce more than about 85 per cent torque. With the conversion factor through the electrical transmission the maximum motor torque available becomes about 60 per cent. However, with proper arrangement for dynamic braking on the motor, satisfactory maneuvering can be obtained.

The author refers to the development work which is being carried out in conjunction with an electronic propulsion system which was considered primarily for use with gas turbines. It is true that the cycloconverter or frequency-changer provides an almost ideal means of controlling the speed and direction of rotation of the propulsion motor without affecting the prime mover; the complications and problems encountered in accomplishing this result are very considerable. The work which has been carried out up to the present time would seem to indicate serious handicaps in size, weight, complication, and reliability when compared with the presently used electric transmission systems.

W. E. Jacobsen (General Electric Company, Schenectady, N. Y.): The paper by Jucarone is directed to a consideration of the different types of electric drives used by the Navy in ships built during the last war, and reviews certain associated application problems. The more controversial field of advantages and disadvantages of electric drive is purposely left to previous literature.

It is readily apparent that the author's choice was a favorable one, and it is equally apparent that he has presented a well-rounded and coherent story of electric drive in modern naval vessels. This discussion will therefore be brief, commenting on only a few items.

The trend to totally enclosed electric propulsion machinery is noteworthy. The Navy has apparently found the added advantages of totally enclosed machinery worth the additional cost. The advantages of this type of machinery are considerable and might well be commended to operators of other classes of vessels. The additional cost is not a large percentage of the total, particularly if proper allowances are made for the corresponding cost of the room ventilating system which must otherwise be provided to secure adequately low ambient temperatures. Too often this compensating economic factor is not worked into the comparison properly.

The Navy's favorable experience with an a-c Diesel electric drive is most interesting. Here in spite of the inherently poor torque conversion during maneuvering when the propeller motor must be operated on its amortisseur winding, it was found possible to make successful reversals with only 50 per cent of the engines in service. This is an important feature in an a-c Diesel electric drive which is generally a multi-engine system, and which may often be operated with less than the full number of engines in service.

The building by the Navy of the same type vessels employing d-c Diesel-machinery on some and a-c Diesel on another, provides one of those rare opportunities for making a dependable comparison. The fact that the a-c machinery installation weighs two-thirds as much, has less than half the losses, and involves less maintenance than the corresponding d-c machinery installation makes its use attractive in spite of certain fundamental disadvantages. The author's conclusion that the use of a-c Diesel electric systems is attractive on ships of medium and higher rated power where maneuvering and towing characteristics are not of primary importance, seems well founded. It remains to be seen, however, whether or not the higher first cost of this system over a nonelectric drive system will permit its use in more than a limited number of vessels.

N. T. Jucarone: Coleman has pointed out that continuous propeller speeds below 30 per cent of rated speed can be obtained in a-c Diesel electric drives by reducing the generator field excitation below normal and operating the propulsion motor as an induction motor. During the trials of the *Sperry*, portable apparatus was installed and continuous operation at propeller speeds down to about 7 per cent of rated speed was found possible when all four generators were supplying power to one shaft. The limitation on minimum speed was determined by the fact that at very low values of generator field excitation, the generators hunted because of the low synchronizing torque.

Jacobsen stressed the trend toward the use of totally-enclosed water-cooled propulsion machines in naval ships. For further discussion on difficulties in providing adequate ventilation and protection against damage from water where open and semi-enclosed machines have been used, refer to the discussion by W. H. Fifer on a recently published AIEE paper.[1]

Overload Protection of Silicone-Insulated Motors for Shipboard Use

J. C. GRIGG
ASSOCIATE AIEE

J. E. WATKINS
NONMEMBER AIEE

AT THE present time, the Bureau of Ships uses overload relays mounted in the controller enclosure as a means of protecting motors from overload, single-phase, and locked-rotor conditions. Both magnetically actuated and thermally actuated relays are used. These overload relays have not been considered too satisfactory for motor protection for a number of reasons. Some of these reasons are as follows:

1. The trip curve of the overload relay does not follow the thermal curve of the motor. The discrepancy in these curves may cause the overload relay to trip before the motor has reached its allowable temperature rise. This is especially true in starting motors with a high torque load which results in a relatively long accelerating period. At other points along the curve, conditions of inadequate protection exist.

2. If the motor and controller are located in different ambient temperatures, as is usually the case aboard ships, the use of overload relays compensated for changes in ambient temperature is necessary. If the motor and controller were located in the same ambient temperature, noncompensated overload relays should be used for the most adequate overload protection to the motor. In order to cut down on the number of types used, all overload relays are presently compensated, thereby sacrificing some motor protection in order to obtain greater standardization.

3. The calibration and rating of the overload relay can be easily tampered with and changed. This provides the operating personnel with a very tempting method of stopping the relay from tripping out on relatively small overloads rather than attempting to locate the actual cause of the trouble. It has been necessary from a manufacturing standpoint to make the overload relays so that the rating can be easily changed because of the fact that a large number of heater coil elements are required for each relay in order to approximate the heating curve of the motors. Even with a large number of overload coils, the relays frequently have to be adjusted after they are installed.

With the advent of silicone-insulated motors requiring different overload relay characteristics than previously encountered, it was considered an opportune time to develop a more effective and satisfactory means for protecting motors from overloads. In protecting motors, the thing which has to be protected against is high temperature. Therefore, it is obvious that the most direct method of protecting a motor against high temperature is a device which will operate directly from the heat of the motor.

Devices which operate from the heat of the motor have been used by a number of manufacturers for fractional horsepower motors with varying degrees of success. With this in mind, the Bureau embarked on a program for the development of thermostatic protectors for a-c silicone-insulated motors.

Specification Requirements

In setting up the development program for a thermostatic protector, the following operational requirements which the protector would be required to meet were specified. These values were based on the characteristics of available motors, the fact that a silicone-insulated motor can operate continuously at 200 degrees centigrade and can operate for a short time at temperatures up to 350 degrees centigrade.

1. With the rotor stalled before the voltage is applied, the protector shall trip before the temperature of the motor windings reaches 350 degrees centigrade when measured by the rise-in-resistance method.

2. With the rotor stalled by an overload after the temperature of the motor windings has reached a steady-state condition of 200 degrees centigrade, the protector shall trip before the temperature of the motor windings reaches 350 degrees centigrade when measured by the rise-in-resistance method.

3. With a 25-per cent overload applied after the temperature of the motor windings has reached a steady-state condition of 200 degrees centigrade, the protector shall trip within 15 minutes after the motor windings reach a temperature of 210 degrees centigrade measured by the rise-in-resistance method.

4. With a 50 per cent overload applied after the temperature of the motor windings has reached a steady-state condition of 200 degrees centigrade, the protector shall trip within six minutes after the motor windings reach a temperature of 210 degrees centigrade when measured by the rise-in-resistance method.

5. With an 80 per cent overload applied after the temperature of the motor windings has reached a steady-state condition of 200 degrees centigrade, the protector shall trip within two minutes after the motor windings reach a temperature of 210 degrees centigrade measured by the rise-in-resistance method.

6. The protectors were otherwise required to meet the specifications for conventional overload relays.

Equipment Description and Test Results

The Bureau of Ships has been working with three manufacturers in the development of thermostatic protectors. These manufacturers are the Spencer Thermostat Company, the Radio Frequency Laboratories, Incorporated, and the White Rodgers Electric Company. The results obtained up to this time indicate that suitable protection for squirrel-cage a-c motors can be obtained by means of a thermostatic device which is relatively simple and reliable.

The thermostatic protector developed by the Radio Frequency Laboratories,

Paper 48-245, recommended by the AIEE marine transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, October 5–7, 1948, Washington, D. C. Manuscript submitted July 14, 1948; made available for printing August 31, 1948.

J. C. Grigg and J. E. Watkins are both with the Bureau of Ships, Navy Department, Washington, D. C.

Incorporated (see Figure 1) consists basically of a thermosensitive element which is inserted in the stator slot along with the motor windings and trip mechanism for breaking the control circuit to stop the motor.

The thermosensitive element is based on the difference in rate of thermal expansion of dissimilar metals. Invar is a metal with a very low rate of expansion; whereas steel expands considerably when heated. An invar rod is placed inside a steel tube with a stop in one end and the trip mechanism at the other end. When the thermosensitive element is heated, the steel tube becomes longer and the invar rod becomes loose. When this element is cooled, the steel tube becomes shorter causing the invar rod to exert a force against the trip mechanism. This force is used to operate the trip mechanism.

The trip mechanism changes this large force and small movement into a smaller force with a larger movement by applying the force from the thermal element to the outer edges of a cup-shaped disk. This force is applied in such a way as to cause the disk to snap inside out at a predetermined pressure. When pressure is released, the disk snaps back to its unstressed position. A small plunger is attached to the center of this disk to operate the contacts. The contacts consist of two stationary contacts and one movable contact. The movable contact is held closed by means of a spring and is opened by the plunger striking it when the disk snaps back into its unstressed position.

In mounting this protector in the motor, the thermosensitive element was inserted in the motor slot between two coils so that there was as small a differential of temperature as possible between the thermosensitive element and the motor windings. The trip mechanism was fastened to the motor frame, and the leads were brought out through the motor terminal box for connection to the control circuit.

In testing this thermostatic protector, it was installed in a silicone-insulated motor (see Figure 2) and tests were conducted to determine whether it met the requirements previously indicated. In addition to these requirements, tests were also conducted to determine if the motor was adequately protected against single-phase conditions. Typical results obtained in these tests are shown in Table I.

The thermostatic protector developed by the White Rodgers Electric Company consists of a sensitive bulb 18 inches long with an inside diameter of 0.120 inch and outside diameter of 0.156 inch. (See Figure 3.) This bulb is filled with a liquid which expands with increase of temperature. This bulb is connected by means of a capillary tube to a diaphragm. On an increase in temperature, the diaphragm moves to open the contacts. The assembly of the contact-making portion of the device is such that snap action of the contacts either to open or close position occurs at a predetermined diaphragm position.

The sensitive bulb was wound around the end turns of the motor winding and securely fastened to the windings by means of insulating tape. The capillary tube was brought out through the motor terminal box to the switch mechanism mounted adjacent to the terminal box. It is expected that the mounting of the switch mechanism inside the terminal box will be feasible for future designs.

Tests as indicated above for the Radio Frequency protector were also conducted on the White Rodgers protector using identical motors. Typical results obtained in these tests are given in Table II.

Table I

	Starting Temperature, Degrees Centigrade	Time to Trip, Minutes: Seconds	Temperature at Trip, Degrees Centigrade	Temperature at Resetting, Degrees Centigrade
25 per cent overload from full load	200	3:05	222	173.5
50 per cent overload from full load	200	0:52	227	175.5
80 per cent overload from full load	200	0:35	225	172.2
Locked rotor from full load	200	0:26	241	172.2
Locked rotor with motor cold	20.5	3:25	264	175.0
Single phase from full load	200	1:12	258	175.0

The thermostatic protector developed by the Spencer Thermostat Company is of the thermostatic disk type (see Figure 4). Each unit consists of a molded glass silicone base on which the contacts, bimetal disk, and a heater are mounted. The protector has two poles with one pole being operated by the tripping element and the other pole being operated by a mechanical linkage between the two poles.

The bimetal disk is cup-shaped and designed so that when it reaches a certain temperature it will snap inside out due to the difference in expansion of the metals. When the disk snaps inside out, it opens the contacts and stops the motor. A heater coil, through which the line current passes, is mounted directly under the disk so that its heat is transmitted to the disk.

Figure 1 (left)

Figure 2 (right)

Figure 3 (left)

Figure 4

The protector is mounted in the motor as close to the winding as possible so that it is at the same ambient temperature as the motor. On small overloads, the design is such that tripping depends almost entirely on the change in ambient temperature due to the increased temperature of the motor windings. As the amount of the overload increases, the heat due to the current through the heater has more effect on the tripping time until at locked rotor the tripping is due almost entirely to the heat from the heater. Two protectors were mounted in the motor in order to insure satisfactory protection on single-phase conditions. Typical results obtained with a motor on which this type of protector was installed are shown in Table III.

Conclusion

In comparing the thermostatic protectors just described, each has certain advantages and disadvantages. The protector developed by the Radio Frequency Laboratories has the advantage of being imbedded in the windings in the motor slot so that it will follow the motor heating curve very closely. However, the disadvantage is that it will probably require that one slot of the motor be made larger than the other slots due to the extra space required. It is also considered doubtful if this protector can be applied successfully to very small motors since a definite movement of the tube due to thermal expansion of steel is required. This fact fixes the tube length for a given temperature rise.

The protector developed by the White Rodgers Electric Company has the advantage of ease of installation. However, it has the disadvantage of having some time lag between the actual motor temperature and the temperature of the protector.

The protector developed by the Spencer Thermostat Company has the advantage of having very fast action on high values of overload or on locked-rotor conditions. In fact, the tripping time on the model tested should be increased to allow full utilization of the motor. This protector, however, has the disadvantage of partially depending on motor current for protection. This will result in the requirement of current transformers for large sizes of motors and may result in a large assortment of heater coils being required to cover the entire range of motor ratings.

From the foregoing tests, it can be seen that it is possible to protect a squirrel-cage induction motor from overloads, single-phasing and locked-rotor conditions by means of thermostatic protectors.

There are some disadvantages in the use of thermostatic protectors. One disadvantage is that control wiring must be run to the motor. Also, space must be found inside the motor enclosure for the thermally sensitive device. In addition, the reset time of the motor protector is greater than that of the conventional thermal overload relay. The first disadvantages can be partially overcome by the use of multiconductor cables to eliminate extra control wires. With connections for the protector brought out to the motor terminal box, extra motor wiring during installation will not be a particular hardship. Since, as indicated herein, protectors of small physical size can be built, it is believed that if the use of a protector is considered in the original design of the motor, the finding of space for the protector will not noticeably penalize the design of the motor. It is felt that in applications where the reset time lag cannot be tolerated, emergency operation of the motor can be obtained by by-passing the thermostatic protector contacts.

These disadvantages are considered to be outweighed by the more adequate protection afforded silicone-insulated motors against overheating due to any cause. Furthermore, it is considered that fewer types of devices can be used to protect

Table II. Protector Set to Trip at 210 Degrees Centigrade

the many ratings and sizes of motors used by the Navy.

The applying of thermostatic protectors to class-*A* insulated motors presents additional problems since the smaller range of operating temperature requires more sensitivity and speed of response. However, it is believed that adequate protection for such motors can be obtained using designs similar to those indicated above.

The Bureau of Ships is presently applying a number of thermostatic protective devices to silicone-insulated motors aboard vessels to determine their adequacy under actual operating conditions. It is expected that if data being obtained prove satisfactory, these protectors will be used in future ship designs.

Discussion

V. G. Vaughan (Spencer Thermostat Company, Attleboro, Mass.): I am particularly interested in the comment regarding the disadvantages of the inherent overheat protector that must respond to motor current.

In order to protect the motor when the rotor is locked during high running overloads, it is necessary to get heat into the protector faster than the normal flow of heat from the copper to the motor winding through the insulation to the protector. When current flows through the protector, this current furnishes heat to the protector so that the protector heats at the same rate as the motor winding. I, therefore, consider it a definite advantage to have the motor current flow through the protector.

Today we have learned some of the underlying fundamentals that allow us to design protectors that will meet almost any condition. By that, I mean we can control the locked rotor characteristics independent of the running loads, and correspondingly, we can control the overload characteristics independent of either locked rotor or running loads. On ultimate trip we might have a motor cutoff at 200 degrees centigrade and on overload we can arrange it so that on high overload we might cutoff as low as 170 degrees centigrade, or we might design the protector so that it would allow the motor to carry high overloads for short time and not cutoff before it attained temperatures of 210 degrees. These devices are not available for these high temperatures. As a matter of fact, they are not necessarily available in all ratings for 125 degrees centrigrade, (Class "A" insulation limits) but as indicated we have learned some of the underlying principles which lead us to believe that we can accomplish these ends.

J. C. Grigg: It is agreed that by using the protector as developed by the Spencer Thermostat Company, it is possible to vary the winding temperature on which the protector operates on high overloads by the use of different heater coils. However, the disadvantage of using heater coils in this device is that for large size motors, current transformers will be required in order to keep the current through the heater at a reasonable value. Also, the use of heaters would probably result in a very large number of heater coils being required to cover the entire range of motor ratings and types. This large number of heaters would complicate the stocking and supply problem of overload protectors considerably.

Effective Resistance and Inductance of 3-Conductor Shipboard Power Cables

SAMUEL D. SUMMERS
MEMBER AIEE

Synopsis: The effective resistance and inductance of 3-conductor shipboard power cables are measured at frequencies up to 800 cycles per second. The effects of conductor spacing, steel armor, and adjacent magnetic materials are described. The results indicate that the effective resistance is increased greatly as the conductor separation is reduced and that both the steel armor on the cables and other adjacent magnetic materials increase the effective resistance and inductance of the cable.

IN studying the general problem of weight reduction of shipboard equipment, investigation was made of the advantages of higher frequency electric power. A study of the transmission characteristics of 3-conductor power cable was made as a part of this investigation. The characteristics of particular interest which are the subject of this paper are the effective resistance and inductance of conductor cables when used in phase circuits.

In an isolated conductor carrying alternating current, the skin effect causes a nonuniform current distribution which is symmetrical with respect to the center of the conductor. However, if the conductors of the circuit are in close proximity as in the case of a multiconductor cable, there results an asymmetrical distribution of current. For example, in a return circuit of two closely spaced parallel conductors, the current density is increased on the sides of the conductors nearest each other. This proximity effect causes an increase in the effective resistance and a decrease of the effective inductance of the conductors forming the circuits. These effects are functions of the size and spacing of conductors and of the frequency of the currents.

Formulas which take into account this proximity effect have been derived for the effective resistance and inductance of two closely spaced parallel round wires in a single-phase circuit,[1,2] and for three equally spaced round wires in a 3-phase circuit.[2,3] However, their application is laborious and the accuracy when applied to a power cable of stranded conductors is questionable, especially since it is known also that these characteristics are affected by the armor and shielding on the cable, by adjacent conducting and magnetic materials and by the spiralling of strands and conductors.

The proximity effect in conductors on a single-phase circuit was studied experimentally by A. E. Kennelly, F. A. Laws and P. H. Pierce[4] in 1915 as a part of a general investigation of skin effect in conductors. The proximity effect in several 3-conductor underground power cables was measured by E. H. Salter, G. B. Shanklin and R. J. Wiseman[5] in 1934. However, it is evident that the effective resistance and inductance of 3-conductor cable are dependent upon so many factors that extrapolation of data from one type and size of cable to another is of questionable accuracy and would perhaps lead to serious error. For these reasons, direct measurement of the effective resistance and inductance was judged necessary to obtain the desired characteristics of the cables.

Method of Test

Since the effective resistance and inductance of a 3-conductor cable depend upon the phase relation of the currents in the conductors, it is necessary that the test circuit make use of balanced 3-phase currents. The circuit arrangement and the method of measurement used in the tests reported here are similar to that described in reference 5. The circuit used is shown in Figure 1.

As a maximum frequency chosen for this investigation was 800 cycles per

H	6	59,200	37		1.45	Al tape (0.004 inch) under Al armor

second, one of the difficulties encountered was obtaining a suitable power source of adequate current capacity. After some preliminary experimentation, it was found that both the effective inductance and resistance were independent of cable current except for a slight saturation effect in the steel armor of the cable and in adjacent magnetic materials. For this reason, and because of the limitation in current capacity of the available equipment, the cable currents used in these tests were less than the normal rated currents of some of the larger cables tested.

The source of voltage selected was a 3-phase 208/120-volt 9-kva variable-speed (4,000–8,000) rpm aircraft alternator. The voltage was stepped down through three Y-connected variable ratio autotransformers, rated 110-volt, 5-kva 60-cycle, and a bank of three Y-Y connected transformers rated 25-kva 575–115 volt, 60-cycle. The low-voltage output of these transformers was applied to one end of the cable, the conductors at the other end being connected together with a special low resistance connector to form a Y-system. The line currents were metered through three current transformers. Balanced line currents were obtained by adjusting the auto transformers.

Cable test lengths were approximately 25 feet and were supported on a wood platform 18 inches above a concrete floor except where otherwise noted. A potential stud was attached to each of the conductors near the source end of the cable, shielding and armor were carefully removed from the area around the stud to avoid electrical connection with it.

The effective resistance and inductance of each conductor length between the potential stud and the short circuiting connector were measured by means of a bridge-like circuit, by comparing the resistive and reactive component voltage drops in the conductor with the voltage drops produced by the secondary current of the current transformer flowing through a standard noninductive variable resistance and a standard variable mutual inductance respectively. For the convenience of the reader the circuit theory and the derivation of formulas used are given in the Appendix

In order to avoid stray induced voltages in the detector circuit of the bridge, the detector circuit was returned to a neutral created by three 100-ohm Y-connected resistors rather than to the neutral formed by the junction of the three conductors of the cable. All leads in the detector circuit were made of shielded twisted pair and precaution was used in arranging leads physically to avoid induced voltages in the detector circuit.

Although the wave form of the generator was approximately sinusoidal, the measurement of the effective resistance and inductance was not affected by any distortion present in the voltage since the bridge balance was obtained for the fundamental frequency only.

The metering circuit was switched into the secondary of each current transformer in turn and the effective resistance and inductance of each conductor of the cable were thus obtained. The direct current resistance of the conductors of the cable was measured by means of a Kelvin double bridge.

Results of Tests

The effective resistances of the three conductors of the cables were generally found to be unequal. This inequality seemed to result from the unequal spacing of the conductors in the cable. This conclusion is borne out by the fact that the conductor separation measured from several cable sections showed considerable inequality and by the results of this investigation which indicate that the effective resistance is critically affected by conductor spacing.

Therefore, for the purpose of comparison, the values of effective inductance and the skin effect resistance ratio given herein represent the averages for the three conductors of the cable. In order to make comparison of effective resistance of the cables of different sizes and construction under the several conditions of test, the skin effect resistance ratio R/R_o is used in this paper rather than the ohmic value of the effective resistance. Although the usual increase in skin effect resistance ratio with increased frequency is noted in this report, attention is directed to the proximity effect of conductors and to the effect of armor and adjacent magnetic materials on both the skin effect resistance ratio and the effective inductance.

The pertinent information concerning the cables tested is listed in Table I. Ref-

Figure 2. The effect of frequency on the skin effect resistance ratio of cables of the same conductor size but with different conductor separation

Figure 3. The effect of frequency on the effective inductance of cables of the same conductor size, but with different conductor separation

Figure 4. The effect of conductor separation on the skin effect resistance ratio for cables of the same size

Figure 6. The effect of frequency on the effective inductance of cables of different size

erence to the particular cables described in this table is by the cable designation A, B, C and so forth.

The conductors of cables A, B, C, D, and E are of one size except for minor differences due to manufacture. However the differences in conductor separation, shielding, armor and, in one cable, to the use of strand interstitial material cause a wide variation in the effective resistance and inductance of these cables. This variation is shown in Figures 2 and 3. Primary among these factors which control the effective resistance and inductance is the conductor separation. The effect of conductor separation on the skin effect resistance ratio is shown in Figure 4, in which it will be noted that the proximity effect of small separation causes a very high ratio.

It will be seen in Figure 4 that although cable E has a very small separation of conductors, the skin effect ratio is extremely low. This apparent anomaly is explained by the fact that the particular strand interstitial material, a rubber-like synthetic, actually serves as a partial insulator between adjacent layers of strands so that the conductor behaves as if the individual strands were coated with a poor insulator. This partial insulation was verified by a continuity test between strands on short lengths (two feet) of the cable. A complete separation of interlayer strands would tend to reduce the proximity effect which would result in lower effective resistance. While a small separation of conductors causes the effective resistance to increase rapidly as the frequency increases, it also causes the effective inductance to decrease as the frequency increases. See the curves of cable C in Figures 2 and 3.

The skin effect resistance ratio versus frequency for cables F and G are shown in Figure 5. These cables differ greatly in area and the curves serve to illustrate the effect of conductor size on the effective resistance of a cable.

To illustrate the magnitude of the proximity effect in 3-conductor cables, the skin effect resistance ratio for an isolated solid conductor of an area equivalent to that of a conductor of cable G is shown by curve I in Figure 5, the data for which were calculated by well-known methods. The difference between this curve and that for cable G is due largely to the proximity effect and in a minor way to the effect of the steel armor on the cable.

The effective inductance of cables F and G are shown as function of frequency in Figure 6. Here it will be observed that the inductance of the large cable falls off rapidly as the frequency increases.

The characteristics of a 6-conductor cable when carrying 3-phase currents were measured during this investigation. The two symmetrical arrangements of conductors used in the tests were:

1. Two adjacent conductors in parallel.
2. Two diametrically opposite conductors in parallel.

The skin effect resistance ratio for these two arrangements of conductors is shown in Figure 7 as a function of frequency. It will be noted that the skin effect resistance ratio is considerably lower when the diametrically opposite conductors are operated in parallel.

The effective inductance for these two arrangements is shown in Figure 8 as a function of frequency. From these curves it will be seen that with the diametrically opposite conductors in parallel the effective inductance is approximately one-half as great as when the adjacent conductors are in parallel.

A comparison of these results with characteristics of 3-conductor cables indicates that a saving in copper and improved line regulation can be obtained by using a 6-conductor cable on 3-phase operation instead of the conventional 3-conductor cable. This improvement increases with the frequency.

Figures 9 and 10 show the effect of ad-

Figure 7. The effect of frequency and conductor grouping on the skin effect resistance ratio of a 6-conductor cable when used in a 3-phase power circuit

Figure 8. The effect of frequency and conductor grouping on the effective inductance of a 6-conductor cable when used in a 3-phase power circuit

Figure 10. The effect of adjacent magnet material on the effective inductance of an unarmored cable

Figure 9. The effect of adjacent magnetic material on the skin effect resistance ratio for an unarmored cable

Figure 11. The effect of steel armor and other adjacent magnetic material on the skin effect resistance ratio of a cable

jacent magnetic materials on the effective resistance and inductance of cable A, which is unarmored but has an aluminum shield under the cable sheath. These curves show that both the effective resistances and inductance are increased by the cable being in contact with a steel plate. This is due to the eddy current losses in the steel plate being reflected into the conductor and in the case of the effective inductance to the fact that the steel plate increases the flux linkages of the conductors.

Figures 11 and 12 show the effect of adjacent magnetic material on the effective resistance and inductance of an armored cable and the effect of the armor itself on these characteristics. In these figures the difference between curves 1 and 2 shows the increase in skin effect resistance ratio and the effective inductance due to the armored cable being placed on a 1/4-inch steel plate. The difference between curves 3 and 4 shows the increase in skin effect resistance ratio and in the effective inductance due to the unarmored cable being placed on the steel plate. The difference between curves 2 and 4 shows the decrease in skin effect resistance ratio and in the effective inductance when the armor is removed while the cable is supported on wood. The difference between the curves 1 and 3 shows the decrease in skin effect resistance ratio and in the effective inductance when the armor is removed while the cable is supported on a 1/4-inch steel plate.

Figures 9, 10, 11 and 12 indicate that both steel armor and other adjacent magnetic materials increase the effective resistance and inductance of a 3-conductor cable.

Accuracy of Measurement

The accuracy of the measurement of the effective resistance and inductance depends upon the accuracy of the standard resistances, the standard mutual inductance and the ratio of the current transformer in the circuit. The precision of the instruments used assures an error not greater than 1 per cent in the measurement of effect resistance. Although the detector circuit was capable of a precise balance, inability to read the scale of the inductometer accurately resulted in a larger error in the effective inductance. Because extraneous induced voltages in the detector circuit tend to create a false balance and therefore an error in both effective resistance and inductance, care was used in locating equipment and circuit leads to avoid this source of error.

As a check on the accuracy of measurement, the voltage drop in the conductors of cables was measured with a special calibrated voltmeter and this voltage compared with the calculated impedance drop in the conductor. The result of such measurement for cable G is shown in Table II.

Despite the fact that errors in the measurement of effective inductance appear almost directly as errors in calculated voltage as a result of the low power factor, the reasonable agreement between measured and calculated voltages would indicate that a reasonable accuracy of measurement of both effective resistance and inductance obtains.

Table II. Comparison of Calculated and Measured Voltages for One Conductor of Cable G

Frequency, cps	Cable Current, Amperes	Effective Resistance, Ohms	Effective Inductance, (mh)	Calculated Impedance Drop, Volts	Measured Voltage Drop, Volts	Ratio of Voltages

Figure 12. The effect of steel armor and other adjacent magnetic material on the effective inductance of a cable

Conclusions

An increase in the effective resistance of a 3-conductor cable is caused by the proximity of the conductors of the cable. This proximity effect increases as the size of conductor and the frequency of current increase and as the conductor spacing decreases. The proximity effect also causes the effective inductance to be decreased under the same conditions.

A 6-conductor cable when operated with its diametrically opposite conductor in parallel in a 3-phase circuit, shows lower effective resistance and inductance than larger 3-conductor cables.

The steel armor on a cable and adjacent magnetic materials cause the effective inductance and resistance of a cable to be increased.

Because of the many factors which govern the effective resistance and inductance of a 3-conductor cable, experimental measurement seems to be the only satisfactory means of obtaining these characteristics.

Appendix. Derivation of Equations for Use in Calculating Effective Resistance and Inductance of a 3-Conductor Cable

The circuit used in the measurement of the effective resistance and inductance of a 3-conductor cable is shown in Figure 1. The essential portion of this diagram is shown also in Figure 13 to illustrate the derivation of the equations used in the calculation of the effective resistance and inductance of a 3-conductor cable. In this circuit, balanced 3-phase currents flow in the three conductors of the cable. Measurements are made on each of the conductors separately. The current (I_a) in conductor A produces a voltage drop (V_{an}) between the point a and the neutral n. This voltage consists of a resistive component (I_aR_a) in phase with the current and a reactive component (I_aX_a) in quadrature with the current.

The current (I_s) in the secondary of the current transformer flows through the non-inductive resistance network consisting of the resistors R, R_1 and R_2, producing a resistive voltage drop (V_{bd}) between the points b and c. This secondary current flowing in the primary of the standard mutual inductometer induces a quadrature voltage (V_{cd}) in its secondary.

The magnitudes of V_{bd} and V_{cd} are independently adjustable by means of the variables R_1, R_2, and the mutual inductance M. The magnitude and phase of the total voltage V_{bd}, therefore, are adjustable and, with the proper connection of current transformer and inductometer, V_{bd} can be made equal to and in phase opposition with V_{an}. This condition will result in zero voltage at the terminals of the cathode-ray oscilloscope which is used as a null indicator. The vector diagram for these voltages and currents at this condition of balance is shown in Figure 14.

Because of the phase angle error, the secondary current in the current transformer is displaced by an angle from the primary current.

In Figure 14 the following relations may be seen:

$$V_{bd} = V_{an} \tag{1}$$

Figure 13. Basic circuit diagram for the measurement of the effective resistance and inductance of a 3-conductor cable

Figure 14. Phase relations of currents and voltages in circuit for measurement of effective resistance and inductance of a 3-conductor cable

$$I_aR_a = V_{an}\cos\theta \tag{2}$$

$$I_sR_s = V_b = V_{bd}\cos(\theta-\beta) = V_{an}\cos(\theta-\beta) \tag{3}$$

where R_s is equivalent resistance between points b and c of the resistance network; and

$$I_aX_a = V_{an}\sin\theta \tag{4}$$

$$I_sX_s = V_{cd} = V_{bd}\sin(\theta-\beta) = V_{an}\sin(\theta-\beta) \tag{5}$$

where

$X_s = 2\pi fM$ and M = mutual inductance of the inductometer.

Dividing equation 3 by equation 2 gives

$$\frac{I_sR_s}{I_aR_a} = \frac{V_{bd}\cos(\theta-\beta)}{V_{an}\cos\theta} = \frac{\cos(\theta-\beta)}{\cos\theta} = \frac{\cos\theta\cos\beta + \sin\theta\sin\beta}{\cos\theta}$$

Substituting

$$\frac{I_s}{I_a} = \frac{1}{r}$$

where r true ratio of current transformer, gives

$$\frac{R_s}{rR_a} = \frac{\cos\theta\cos\beta + \sin\theta\sin\beta}{\cos\theta}$$

Since β, the phase angle error of the current transformer, is less than 10 minutes, $\cos\beta$ is almost equal to unity. Then

$$\frac{R_s}{rR_a} = 1 + \tan\theta\sin\beta \tag{6}$$

Dividing equation 5 by equation 4 and substituting $\frac{I_s}{I_a} = \frac{1}{r}$, gives

$$\frac{X_s}{rX_a} = \frac{\sin(\theta-\beta)}{\sin\theta} = \frac{\sin\theta\cos\beta - \cos\theta\sin\beta}{\sin\theta}$$

$$\frac{X_s}{rX_a} = \cos\beta - \frac{\sin\beta}{\tan\theta} = 1 - \frac{\sin\beta}{\tan\theta} \tag{7}$$

Substituting

$\frac{X_s}{R_s} = \tan\theta$ in equation 6 and 7 gives

$$\frac{R_s}{rR_c} = 1 + \frac{X_s}{R_s}\sin\beta \tag{6a}$$

$$\frac{X_s}{rX_c} = 1 - \frac{R_s}{X_s}\sin\beta \tag{7a}$$

When equations 6a and 7a are solved simultaneously for R_c and X_c, the result is

$$R_c = \frac{\frac{R_s}{r} - \frac{X_s \sin}{r}}{(1 + \sin^2\beta)} \tag{8}$$

$$X_c = \frac{\frac{X_s}{r} + \frac{R_s \sin\beta}{r}}{(1 + \sin^2\beta)} \tag{9}$$

Since β is less than 10 minutes, $\sin^2\beta$ is negligible, and equations 8 and 9 reduce to

$$R_c = \frac{R_s - X_s \sin\beta}{r} \text{ and } X_c = \frac{X_s + R_s \sin\beta}{r}$$

A further approximation may be made with error of less than 0.1 per cent by dropping the term containing $\sin\beta$. Then

$$R_c = \frac{R_s}{r} \tag{8a}$$

and

$$X = \frac{X_s}{r} \tag{9a}$$

The equivalent resistance R_s between points b and c on the resistance network is

$$R_s = \frac{R_2 R}{R_1 + R_2 + R}$$

and since R is negligibly small compared to $R_1 + R_2$

$$R_s = \frac{R_2 R}{R_1 + R_2} \tag{10}$$

Substituting this in equation 8a gives

$$R_c = \frac{R_2 R}{r(R_1 + R_2)}$$

Since R, R_1, R_2 and r are known, R_c may be calculated readily.

$$X_c = 2\pi f L_c \quad \text{and} \quad X_s = 2\pi f M$$

Substituting these in equation 9a gives

$$2\pi f L_c = \frac{2\pi f M}{r} \quad \text{or} \quad L_c = \frac{M}{r}$$

Since M and r are known, L_c may be calculated readily.

Steady-State Analysis of Aircraft D-C Generators

ERNEST VAN VALKENBURG
NONMEMBER AIEE

WHITNEY MATTHEWS
MEMBER AIEE

Synopsis: A practical method is developed for obtaining analytical expressions to represent the steady-state electromagnetic characteristics of a d-c generator. The terminal voltage of a separately excited d-c generator can be computed as a function of steady-state conditions of excitation, load, and speed when certain physical and empirical constants of the machine are known. The analysis leads to equations which can be applied to the condition of self-excitation. Applications of this mathematical tool to several aircraft generators indicate an accuracy approximating that of physical measurement when hysteresis effects are neglected.

IT IS often desirable and sometimes necessary to apply a mathematical analysis to the solution of certain problems involving a d-c generator and its associated control system. Specifically, the solutions to many d-c dynamo problems would be less complex providing there were a simple, yet accurate, means for expressing mathematically the machine's electromagnetic characteristics. This mathematical investigation originated with the necessity of analyzing the factors affecting the voltage regulation of aircraft d-c generators. It was believed that this problem could be approached with greater certainty, if trial and error processes could be abandoned for a direct mathematical investigation. Such a mathematical tool may prove applicable to certain aspects of dynamo design, problems of voltage, load, or speed control and theoretical study of magnetic circuits. The purpose of this paper, therefore, is to present the development of this mathematical analysis and associate it with established theories of d-c machines.

A satisfactory analytical representation for the steady-state characteristics of aircraft d-c generators has been developed. The basic theories involved are sufficiently general so that application to other types of generators can be made easily. Once an analysis has been established for the steady-state conditions, it seems possible that generator build-up, optimum voltage and load for maximum efficiency or minimum weight, optimum brush positions, and so forth, could be investigated more thoroughly than at present. Extension of the theory to treat transients has not been attempted, and it is questionable whether such an attempt would prove of value.

Sometimes an exact mathematical representation of a nonlinear physical system becomes so involved and tedious that such an approach is impractical. An approximate analysis using empirical equations, however, often results in a relatively simple solution having a practical degree of accuracy. This is true for d-c generators. All the steady-state characteristics, which involve the magnetic circuit, are nonlinear because of the magnetic saturation property of ferromagnetic materials. Thus, it is expedient to represent the magnetization curve for any given machine by an empirical equation. Many attempts have been made to find an algebraic or transcendental function that would express this magnetization characteristic satisfactorily, but most of these equations either produce large errors over portions of the curve, or become too complex to be practical. Probably the most used function is that obtained by Froelich;[1] yet this equation is reasonably accurate over only a limited region. Ryder[2] has conceived an expression involving the Gudermannian function. This equation determines a curve with satisfactory accuracy, but an exact integral of the function has not been found. This fact impairs its usefulness in certain applications. In searching for a more useful relationship, a hyperbolic-tangent function has been derived which adequately represents the magnetization characteristics of aircraft generators, and which is also mathematically flexible.

Generator Terminal Voltage

The steady-state terminal voltage of a d-c generator may be represented by

$$E_t = K\Phi n - E_a \tag{1}$$

where Φ is the flux, and n is the speed in rpm. $K\Phi n$ is the generated voltage, and E_a is the combined IR drop and contact potentials in the armature circuit (including any series coils) as a result of load current. When E_t is expressed in volts, the constant becomes

$$K = \frac{ZP}{60 \times 10^8 a} \tag{2}$$

where Z is the number of armature conductors, P is the number of field poles, and a is the number of parallel armature current paths.

Nonlinearity is introduced when flux is expressed as a function of magnetomotive force, or ampere-turns of the field. A typical magnetization characteristic for an aircraft generator is shown in Figure 1. The shape of these curves depends upon the history of the iron in the machine. To keep the theory as general as possible, it is assumed that the iron has been previously saturated creating a residual flux. The condition of no residual flux will then be a special case. (See Appendix II). The upper and lower curves of Figure 1 represent the limits of the minor hysteresis effects due to normal operation along the upper trace of a

Paper 48-250, recommended by the AIEE air transportation committee and approved by the AIEE technical program committee for presentation at the AIEE Middle Eastern District meeting, Washington, D. C., October 5-7, 1948. Manuscript submitted March 10, 1948; made available for printing August 12, 1948.

ERNEST VAN VALKENBURG and WHITNEY MATTHEWS are both with the Naval Research Laboratory, Washington, D. C.

complete hysteresis loop. To simplify the analysis, let the mean of these two curves represent the relationship of flux and excitation (ampere-turns). This is equivalent to neglecting the minor hysteresis effects. The maximum error introduced is about two per cent of the normal total flux for aircraft generators.

No-Load Saturation Characteristic

The empirical equation developed for expressing the no-load air-gap flux, ϕ, as a function of field excitation is

$$\phi = A \tanh (BN_fI_f + C) + D \qquad (3)$$

where N_fI_f is the separately excited shunt field ampere-turns per pair of poles. The empirical constants A, B, C, and D can be determined accurately for a generator by solving four specific simultaneous equations (see Appendix II). This function was chosen because of the similar shapes of the hyperbolic-tangent and magnetization curves, and the use of four constants provides satisfactory flexibility for curve fitting. Other advantages of this expression are that it is integrable, and field excitation can be expressed explicitly.

The no-load terminal voltage with the shunt field separately excited is then

$$E_t = Kn(A \tanh [BN_fI_f + C] + D) \qquad (4)$$

Figure 2 displays the exactness of equation 4 when applied to three aircraft generators. The maximum error in computed values from the measured characteristic is about one per cent of the normal output voltage for characteristics A and C, and less than two per cent for characteristic B. This error is less than the deviations due to hysteresis, which are being neglected.

Figure 3 indicates the result of a reasonable attempt to apply Froelich's equation to the characteristic B of Figure 2. Here the maximum error is about ten per cent. Furthermore, this error increases at greater excitations, which will become critical under load conditions.

Introducing Armature Current

The steady-state load characteristics can be expressed mathematically, provided an analysis of the effects of armature current can be incorporated in equation 4. Two such effects are known to occur in d-c generators. These are the IR drop and the magnetomotive force of armature reaction. The latter is divided into "direct" and "cross" axis components.

Direct-axis armature reaction may cause demagnetization or magnetization depending on the direction of the brush shift. The magnitude of this force is determined by the ampere-turns included in the double arc between the brush position and the geometric neutral axis.[1] The magnitude of this force per pair of field poles in ampere-turns is represented by N_dI_a, where I_a is the total armature current and

$$N_d = \frac{4\alpha Z}{360\, Pa} \qquad (5)$$

α is the forward brush soift angle expressed in electrical degrees. Since this force directly opposes the main field, the resultant field excitation is $N_fI_f - N_dI_a$. Likewise, a brush shift against rotation, which has been observed in some aircraft generators, makes the absolute value of N_dI_a negative and increases magnetization.

The demagnetizing component due to cross ampere-turns results from the unequal saturation of the leading and trailing portions of the main field pole shoes. Armature current creates flux paths through each field pole, two air-gaps, and the armature as shown by

Figure 1. Typical magnetization characteristic

Figure 2. No-load saturation characteristics

Generator A—6 kw machine at 3,500 rpm
Generator B—2 kw machine at 3,500 rpm
Generator C—2 kw machine at 6,000 rpm

Figure 3. Application of Froelich's equation

Figure 4. Flux paths
M—main field paths
C—cross field paths

path C, Figure 4. The reluctance of these paths is approximately the same as the main field paths. In practice, the error in assuming them equal is negligible; therefore, the flux distribution with respect to armature ampere-turns along the air-gap due to cross-magnetization may be represented by the no-load magnetization curve, shown in Figure 5. The effective demagnetization is then proportional to the difference of the areas A_1 and A_2.

That this demagnetizing component is equivalent to the necessary shift of the dimension $2N_cI_a$ $(N_fI_f - N_1I_1)$ to make area A'_1 equal A'_2, Figure 6, has been suggested by Langsdorf.[8] He demonstrates this equivalence mathematically by integrating Froelich's equation. Through a similar integration of equation 3, the following expression for total flux, Φ, under load conditions is obtained. This includes also the effect of the direct axis component of armature reaction (see Appendix III).

$$\Phi = \frac{A}{2BN_cI_a} \times \log_e \left[\frac{\cosh\,[B(N_fI_f - N_aI_a + N_cI_a) + C]}{\cosh\,[B(N_fI_f - N_aI_a - N_cI_a) + C]} \right] + D \tag{6}$$

where N_cI_a is the cross ampere-turns per pole. The reluctance of any cross flux paths extending beyond the boundaries of a pole shoe becomes very great. Therefore, only a slight error is introduced by considering just the armature conductors spanned by the pole shoes. Thus, for a pair of field poles

$$N_c = \frac{2\gamma Z}{360\,Pa} \tag{7}$$

where γ is the angle, measured in electrical degrees, of the arc subtended by a field-pole shoe. The generator terminal voltage is then

$$E_t = K\Phi n - E_a \tag{8}$$

Of the three effects, E_a is the most pronounced. E_a is the measured electrical potential difference resulting from armature current. This voltage is not only an IR drop, but includes contact potentials developed at the brush and commutator surfaces. For obvious reasons no attempt has been made to express the latter inconstant phenomenon mathematically; it is more practical to determine the magnitude of E_a from a series of linear characteristics which approximate the measured values as shown in Figure 7. The measured values are terminal voltages obtained when the armature is supplied with current from an external source and operated with all field poles removed.

Figure 8 indicates the results of applying equations 6 and 8 to an aircraft generator having no windings in series with the armature. The maximum error within the operating range (20 to 40 volts) is less than ±1 volt, or about ±3 per cent of the output voltage. If a generator is compounded, the additional magnetomotive force created by armature current must be added to the shunt field excitation.

Generators having either compensating coils, commutating poles, or both, do not complicate this analysis, providing these devices are symmetrical with the main field structure. The characteristics of a perfectly compensated separately excited machine would be represented by equation 4 minus E_a for any load condition. Commutating poles permit the brushes to be located on the no-load neutral axis without sparking under load conditions, thus eliminating direct-axis armature reaction. Practically, the compensating coils of a machine will not perfectly annul the demagnetization due to cross ampere-turns. Therefore, the magnitude of N_cI_a for a compensated generator becomes the absolute difference between the effective ampere-turns of the compensation and the armature ampere-turns contributing to cross-magnetization. The effective turns of the compensation is equal to half the number of compensating conductors per pair of poles, divided by the number of parallel compensating current paths. Figure 9 typifies the accuracy of applying equations 6 and 8 to a generator having compensating windings and commutating poles. The brushes of this machine have a backward shift which produces cumulative compounding at load conditions.

Figure 5 (left). Air-gap flux distribution caused by cross-magnetization

Figure 6. Analysis of cross-magnetization

The maximum error is ≐0.7 volt in the rated operating range.

Detailed Analysis of Equation 6

If equation 6 satisfies all conditions of cross-magnetization, then it must be equal to equation 3 when the armature current is zero. Also, according to the preceding paragraph, the effective N_c can theoretically vanish through perfect compensation of cross-magnetization. For either of these conditions, equation 6 becomes indeterminate. The limits, however, as I_a or N_c approach zero are as follows:

$$\lim_{I_a \to 0} \Phi = \lim_{I_a \to 0} \frac{\dfrac{d(A \log_e Y)}{dI_a}}{\dfrac{d(2BN_cI_a)}{dI_a}} + D$$

$$= A \tanh (BN_fI_f + C) + D = \phi \qquad (9)$$

where

$$Y = \frac{\cosh [B(N_fI_f - N_dI_a + N_cI_a) + C]}{\cosh [B(N_fI_f - N_dI_a - N_cI_a) + C]}$$

and, likewise,

$$\lim_{N_c \to 0} \Phi = A \tanh (B[N_fI_f - N_dI_a] + C) + D \qquad (10)$$

Thus, these conditions are satisfied.

It should be noted that for large magnitudes of N_cI_a (maximum loads), equation 6 is not rigorously valid. Whenever N_fI_f is less than N_cI_a, the line $2N_cI$ projects into the second quadrant, Figure 10, which indicates that the portions of the magnetization curve in the second and third quadrants must be considered. The function chosen to represent the curve is not absolutely symmetrical to the vertical axis. Equation 3 can be altered to apply to the second and third quadrants as follows:

$$\phi' = A \tanh (BN_fI_f - C) + D + 2A \tanh C \qquad (11)$$

Fortunately, for most applications, equation 3 can be assumed equal to equation 11 without appreciable error (see Appendix III). Under such a condition, equation 6 is acceptable for all loads.

Experience indicates that this assumption of symmetry is permissible for all magnitudes of $2N_cI_a$ less than the excitation required for rated load. The magnitude of $2N_cI_a$ at rated load for generator C, whose characteristics are exhibited in Figure 8, is 825 ampere-turns, yet the error from applying equation 6 is negligible within the operating region. If this error is not negligible, both equations 3 and 11 must be employed to determine the effect of cross-magnetization (see Appendix III).

Inverse Generator Characteristics

For certain applications, it may be desirable to solve equations 4 and 8 explicitly for such variables as field excitation, brush shift, or speed. Such characteristics are derivable. The solution of equations 4 or 8 for speed is obvious. Solving equation 4 for field excitation gives simply

$$N_fI_f = \frac{1}{B} \tanh^{-1} \left[\frac{E_t - D}{AKn} \right] - \frac{C}{B} \qquad (12)$$

or, solving equation 8 for field excitation (Appendix IV) gives

$$N_fI_f = \frac{1}{2B} \log_e \times \left[\frac{\exp [2BN_cI_a(E_t - DKn + AKn + E_a)/(AKn)] - 1}{\exp [2BN_cI_a] - \exp [2BN_cI_a(E_t - DKn + E_a)/(AKn)]} \right] - \frac{C}{B} + N_dI_a \qquad (13)$$

This equation is readily solvable for N_d, which is a function of brush shift. A unique solution of equation 8 for armature current does not exist since E_a, which is expressed algebraically is also a function of armature current The measured and calculated characteristics of field excitation versus load current are shown in Figure 11.

Equation 13 is of particular interest, because it can be applied to a self-excited generator. So far, the analysis has been confined to conditions of separate excitation in order to determine terminal voltage when field current is the independent variable. For the condition of self-excitation, field current becomes interdependent on terminal voltage. That is, for a generator whose shunt field is excited by the terminal voltage,

$$I_f = E_t / R_f \qquad (14)$$

where R_f is the total field circuit resist-

Figure 7. Determination of E_a on generator C

A—8,000 rpm
B—6,000 rpm
C—4,000 rpm

Figure 8. Load characteristics of generator C

A—$I_a = 30$ amperes
B—$I_a = 75$ amperes

ance. Combining equations 13 and 14 gives

$$R_f = \frac{2BE_tN_f}{\log_e\left[\frac{\exp[2BN_dI_a(E_t - DKn + AKn + E_a)/(KnA)] - 1}{\exp[2BN_dI_a(E_t - DKn + E_a)/(KnA)]}\right] - 2C + 2BN_dI_a} \quad (15)$$

Load current is now different from armature current, and equation 15 is applicable at no-load since I_a is not then zero. Thus, by means of equation 15, the field resistance which will satisfy any particular set of steady-state conditions when a generator is self-excited can be computed. Figure 12 shows the results of this application on two aircraft generators. The maximum error has accumulated to ±7 per cent which is the approximate horizontal error of minor hysteresis loops.

Conclusion

It has been demonstrated that the steady-state characteristics of a d-c generator can be represented mathematically to a practical degree of accuracy by using hyperbolic functions. Application of this analysis to a given machine requires the following specific data:

1. The magnetization characteristic or a no-load saturation characteristic at a known speed.
2. The number of field and compensating turns per pair of poles.
3. The number of main field poles.
4. The total number of conductors on the armature.
5. The angle of brush shift and its direction.
6. The angle of the arc subtended by a field pole shoe.
7. The number of parallel current paths in the armature.
8. The number of parallel current paths through any series windings.
9. The armature voltage drop at various loads and speeds.

From these data, the terminal voltage of a separately excited aircraft generator has been computed for any rated conditions of speed, load, and excitation with an accuracy of ±3 per cent. Furthermore, this analysis leads to certain applications involving self-excitation with a maximum error of about seven per cent. The limiting accuracy of this analysis is determined largely by effects due to minor hysteresis loops and erratic contact potentials.

In applications which require only an approximate analysis, equation 3 can be simplified to a pure hyperbolic tangent function. That is, $\phi = A \tanh B(N_fI_f)$. Using this equation, results have been obtained to an accuracy within five per cent error for no-load characteristics.

Only the most simple aircraft generators have been examined. The equations derived are not sufficiently general for application to all generators. For example, only symmetrical field poles have been studied. Asymmetrically shaped pole shoes have a direct effect on the magnitude of cross-magnetization which cannot be directly determined by methods presented here. The analysis can be applied also to machines with series fields. Certain apparent alterations, however, may be necessary to distinguish between armature and load currents. Therefore, successful application of this mathematical analysis is dependent on an investigation of the physical design of the particular type of generator involved.

Appendix I. Symbols

The symbols used in this analysis have been explained as they appeared in the text, but for the convenience of the reader, the following summary is presented.

A, B, C, and D = empirical constants
a = number of parallel armature current paths

Figure 9. Load characteristics of compensated generator A

A—I_a=100 amperes
B—I_a=200 amperes

Figure 10. Analysis of cross-magnetization at small excitations

α = angle of brush lead from the no-load neutral axis
γ = angle of arc subtended by a field pole shoe
E_a = total armature voltage drop due to load current
E_t = terminal voltage
I_a = armature current
I_f = shunt-field current
K = a constant of the generator
N_c = number of effective turns contributing to cross-magnetization
N_d = number of effective turns contributing to direct axis armature reaction
n = speed in rpm
P = number of field poles
R_f = total shunt field resistance
Φ = total air-gap flux at load
ϕ = total air-gap flux at no-load
ϕ' = total air-gap flux at no-load with negative excitation
Z = total number of armature conductors

Appendix II. Determination of Empirical Constants

The empirical constants can be determined by investigating the characteristics of the hyperbolic-tangent function. For the function $Y = \tanh X$, $Y = 0$ when $X = 0$. Therefore, when $N_f I_f = 0$, equation 3, $\phi = A \tanh (BN_f I_f + C) + D$, becomes

$$\phi_r = A \tanh (C) + D \tag{16}$$

where ϕ_r equals the residual flux. For the special case where the curve passes through the origin, ϕ_r is zero, but equation 16 and those that follow are still valid for determining the constants. Likewise, $Y = 1.0000$ for any value of X greater than 5.00. The slope of Y versus X approaches zero so rapidly that even tanh 3.0 = 0.995. For convenience, let tanh 3.0 = 1.0. Then

$$\phi_{max} = A \tanh (3.0) + D = A + D \tag{17}$$

when

$$BN_f I_{max} + C = 3.0 \tag{18}$$

That is, when the field pole becomes saturated, the slope of the magnetization curve can be considered practically zero. This maximum excitation is usually about twice the excitation required for rated load. The point ($N_f I_{max}$, ϕ_{max}) can be predicted sufficiently by extrapolation, if necessary. For an intermediate value of rated excitation, $N_f I_1$, the flux is

$$\phi_1 = A \tanh (BN_f I_1 + C) + D \tag{19}$$

Solving equation 17 for D, and substituting in equation 19 gives

$$\phi_1 = A \tanh (BN_f I_1 + C) + \phi_{max} - A \tag{20}$$

From equations 16 and 17

$$\frac{A = \phi_{max} - \phi_r}{1 - \tanh [C]} \tag{21}$$

Combining equations 18, 20, and 21 yields

$$1 + \frac{\phi_{max} - \phi_1}{\phi_{max} - \phi_r}(\tanh [C] - 1) = \tanh \left[\frac{C(N_f I_{max} - N_f I_1) + 3N_f I_1}{N_f I_{max}} \right] \tag{22}$$

Equation 22 can be solved graphically for the constant, C. There are usually two roots other than 3.0. If no other root than 3.0 exists, point ($N_f I_1$, ϕ_1) should be chosen higher on the curve. Knowing C, substitution in equations 21, 18, and 17 determines A, B, and D, respectively. A trial curve can then be plotted. If this calculated curve does not fit the experimental measurements within about one or two per cent error, it indicates that the point ($N_f I_{max}$, ϕ_{max}) was not determined accurately. An error in any portion of the curve can often be reduced by a slight alteration of one or two of the constants by inspection.

Hyperbolic function tables prepared by the National Bureau of Standards have been found very useful for radian arguments significant to three or more figures.[8,9]

Appendix III. Derivation of Cross-Magnetizing Effect

Demagnetization results from cross-magnetization when the line "GL," Figure 5, is not a straight line. That is, there would be no demagnetizing effect when area "GHJ" equals area "HML," Figure 6. This condition can be satisfied for any ordinate, ϕ, on the curve by shifting the dimension $2_c NI_a$ to the right. Now area G'HJ' = area HM'L'. Thus, for a no-load excitation of $N_f I_f$, and a given armature current, the resultant flux is ϕ. ϕ is the mean value of the ordinates between the limits $NI = X_1$ and $NI = X_4$, or

Figure 11. Inverse characteristics of generator B

A—$E_t = 40$ volts
B—$E_t = 30$ volts
C—$E_t = 20$ volts

$$\phi = \frac{1}{X_4 - X_3} \int_{X_3}^{X_4} \phi d(NI) \quad (23)$$

where

$$\phi = A \tanh (BNI + C) + D \quad (24)$$

Integrating equation 24 gives

$$\int \phi d(NI) = A/B \log_e [\cosh (BNI + C)] + DNI + K' \quad (25)$$

where K' is the constant of integration. Then

$$\Phi = \frac{1}{X_4 - X_3} \times \left[A/B \log_e [\cosh (BNI + C)] + DNI \right]_{X_3}^{X_4} \quad (26)$$

but, $X_4 = N_f I_f + N_c I_a$ and $X_3 = N_f I_f - N_d I_a$. So,

$$\Phi = \frac{A}{2N_c I_a B} \times \log_e \left[\frac{\cosh [B(N_f I_f + N_c I_a) + C]}{\cosh [B(N_f I_f - N_d I_a) + C]} \right] + D \quad (27)$$

Investigation When $N_f I_a$ Is Large

The complete magnetization curve of Figure 10 can be expressed as two functions, one function being valid for positive values of excitation and the other for negative values. These functions are, respectively:

$$\phi = A \tanh (BN_f I_f + C) + D \quad (28)$$

$$\phi' = A \tanh (BN_f I_f - C) + D + 2A \tanh C \quad (29)$$

Recalling that

$$\tanh (BN_f I_f \pm C) = \frac{\tanh (BN_f I_f) \pm \tanh (C)}{1 \pm \tanh (BN_f I_f) \tanh (C)} \quad (30)$$

it is apparent that if both $BN_f I_f$ and C are much less than unity, then

$$\tanh (BN_f I_f \pm C) \approx \tanh (BN_f I_f) \pm \tanh (C) \quad (31)$$

Applying this to equations 28 and 29 yields

$$\phi \approx \phi' \approx A \tanh BN_f I_f + A \tanh C + D \quad (32)$$

If equation 32 is not sufficiently accurate in a particular application, the effect of cross-magnetization can be derived by considering positive and negative magnetomotive forces separately. That is, the areas A'_1 and A'_2 (Figure 10) can be represented by two integrals having the proper limits. In which case,

$$\Phi'(2N_c I_a) = \int_0^{N_f I_f - N_d I_a} \phi' d(NI) + \int_0^{N_f I_f + N_c I_a} \phi d(NI) \quad (33)$$

Figure 12. Self-excitation characteristic

A—generator C, $E_t = 28$ volts
B—generator A, $E_t = 28$ volts

$$\Phi' = \frac{A}{2BN_c I_a} \times \log_e \left[\frac{\cosh [B(N_f I_f + N_c I_a) + C]}{\cosh [B(N_f I_f - N_d I_a) - C]} \right] - \frac{A(N_f I_f) \tanh C}{N_c I_a} + A \tanh C + D \quad (34)$$

Here, however, $N_f I_f$ is not uniquely confined to the logarithm as in equation 27; therefore, equation 34 is very inflexible, and its utility is limited.

Appendix IV. Solution of Equation 8 For $N_f I_f$

Equation 8 can be expanded as

$$E_t = Kn \left(\frac{A}{2BN_c I_a} \times \log_e \left[\frac{\cosh [B(N_f I_f - N_d I_a + N_c I_a) + C]}{\cosh [B(N_f I_f - N_d I_a - N_c I_a) + C]} \right] + D \right) - E_a \quad (35)$$

or, expressed exponentially,

$$\exp [B(N_f I_f - N_d I_a + N_c I_a) + C] + \exp [B(N_f I_f - N_d I_a - N_c I_a) + C] + \exp [-B(N_f I_f - N_d I_a + N_c I_a) - C] = \exp [-B(N_f I_f - N_d I_a - N_c I_a) - C] = \exp [2BN_c I_a(EI + E_a - DKn)/(AKn)] \quad (36)$$

Multiplying both sides of equation 36 by the first term in the numerator and clearing of fractions yields

$$\exp\ [2B(N_f I_f - N_d I_d)+2C]\ \exp\ [2BN_d I_a] + 1 = \exp\ [2B(N_f I_f - N_d I_d)+2C] \times \exp\ [2BN_d I_a(E_t+E_a-DK\pi)/(AK\pi)] + \exp\ [2BN_d I_a(E_t+E_a-DK\pi)/(AK\pi)+2BN_d I_a] \quad (37)$$

Factoring and rearranging gives

$$N_f I_f = \frac{1}{2B}\log_e\left(\frac{\exp\ [2BN_d I_a(E_t+E_a-DK\pi+AK\pi)/(AK\pi)]-\exp\ [2BN_d I_a]-1}{[2BN_d I_a(E_t+E_a-DK\pi)/(AK\pi)]}\right)-\frac{C}{B}+N_d I_a \quad (38)$$

Industrial Electric Resistance Heating

LEE P. HYNES
FELLOW AIEE

IN THE tremendous growth of electric heat for industrial use there have developed several methods of transforming electric power into heat energy. While the basic principle is the same, in that heat is generated by resisting the free flow of electric current, the term "resistance heating" has been applied to describe the method of passing current through a resistance material and transferring this heat by means of conduction and radiation.

Resistance heating is the oldest and most widely used type, but there are many situations where other methods are superior, and the mature engineer will determine accurately the advantages and disadvantages of each and avoid the assumption that a method which has worked for one job is necessarily the logical one for another job, even though they seem at first glance to be similar.

Among the advantages of resistance heating are its inherent efficiency of almost 100 per cent in converting electric power into heat energy, high thermal efficiency in transferring this heat to the work, adaptability to the standard commercial power circuits without expensive transformers, moderate investment cost, and reliable service.

Its principal disadvantages lie in its limitation to temperatures well below those required for some purposes, its limitation in density of heat input where great concentration of heat energy is required at any temperature, and its inability to heat uniformly some materials, such as dielectrics, except by slow conduction through their mass.

Another disadvantage which is also shared by all other methods is the frequent attempt to apply electric heat to a specific job without enough background of experience and without an accurate analysis of all the intricate engineering problems which are involved. The most innocent-looking job has plenty of pitfalls in the industrial electric heating field.

Perhaps we can also say that one disadvantage of resistance heating is that it looks so simple. For many purposes, it is comparatively simple, and the wide use of electric-strip, cartridge, and immersion heaters testifies to their durability in spite of considerable abuse of them by poor application design on the part of the user.

Resistance heating elements are made of a size, shape, and construction to suit the use for which they are intended. By far the greatest number have heat-producing resistors of nickel-chrome alloy wire or ribbon. Electric current flowing through this high-resistance metal creates heat.

Refractory insulation is used to electrically insulate and support the heated resistor. This insulation must have ample dielectric strength at the maximum operating temperature.

Some heating elements have resistors embedded in compressed refractory powder, with a metal sheath enclosure, carrying suitable insulated terminals for the power supply. Enclosed elements of this kind depend to a large extent on conduction for delivering their heat.

Heavy-duty heating elements often have resistors of wire or ribbon supported by performed refractory insulators flexibly mounted to withstand shock and permit free expansion and contraction. Open elements of this kind permit heavy loading and can operate at high temperatures as they deliver most of their heat by radiation. They are well suited for grouping into large assemblies with substantial bus connections.

This construction permits clearances to ground ample for the higher commercial voltages even at elevated temperatures. When inserted into tubes, they form pressure-type units of large heating area.

The more important uses of resistance electric heating are in industrial process equipment where careful engineering design and sound experience have produced highly efficient and reliable results. Some typical examples are: heat-treating furnaces; hot-air recirculating dryers; electric boilers for steam, hot water, dowtherm, and so forth; hot oil heat transfer systems; preheaters for fuel oil; ovens; electric-unit air heaters; electric catalysts; steam superheaters; ice melters; air duct heaters; radiant heaters; and tanks or kettles for pitch, oil, wax, and chemicals.

The correct design of industrial process equipment requires careful analysis of each individual job. The complex problems to be solved include heat transfer, rate of heating, economics, time factors, critical temperatures for materials, corrosion, safety from hazards, code requirements, effective insulation, proper design of automatic controls, and practical labor-saving methods of handling materials in process. These challenge the best efforts of the electrical, mechanical, and chemical engineer and require close co-operation with plant production management. Only through a careful and complete study of each job can really satisfactory performance be assured.

Automatic controls are vital for the proper and economical operation of electric heaters. It is a fallacy to think that close temperature regulation can always be obtained by simply using a sensitive temperature control. In many cases, the rate of heat input must be varied to suit variation in heat demand. If this is not provided for, overshooting and undershooting of temperature will surely result, especially when a variable flow of material of low specific heat is involved as in air and gas heaters, steam superheaters, and conveyor units operating under

Paper 48-247, recommended by the AIEE electric heating committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted April 5, 1948; made available for printing July 29, 1948.

Lee P. Hynes is a consulting engineer, Hynes Electric Heating Process Division, Martin Quaid Company, Philadelphia, Pa.

variable speed or with great changes in load of work per unit of time.

Many engineers are so used to thinking in terms of steam that they fail to realize the basic differences between steam and electric heating. With steam, there is an initial accelerated input of heat when the work is cold due to the high rate of steam condensation. As the temperature rises, this condensation rate drops and heat transfer falls in proportion because the heat gradient drops.

With electric heat, the energy input is practically constant and temperatures rise at a nearly uniform rate because the heat gradient remains substantially constant. It must be remembered that the temperature of an electric heater rises as the ambient temperature surrounding it rises. The heat density rating of an electric heater must be designed for its maximum temperature when operating at the maximum ambient temperature.

A common error in large air-heating units is to assume that a mixing damper can be used to control temperature by means of by-passing the electric heater, as is standard practice for steam heat. Actually no change in electric energy input will result from by-passing the heater as reduced airflow over the heater will result in a corresponding rise of temperature in the air that does pass over it.

Wherever any change of energy input from an electric heater is required, some change of the power input must be made by suitable control means. This may be accomplished in several ways such as change in impressed voltage, change in the number of heater sections in operation or by time cycling.

Many factors must be studied in designing a resistance heating job. Among these are the required maximum kilowatts per hour, the maximum permissible temperature for the heated surfaces in contact with the work being heated, the total area of the heated surface needed to allow the required energy input without exceeding the permissible maximum temperature, the watt density necessary to deliver the required energy input, and the maximum safe temperatures of the heating elements.

The temperature of a heating element depends on the watt density per unit of surface, the maximum heat gradient between the element and the work, and the maximum ambient temperature of the work. It must always be remembered that the operating temperature of an electric heater is not a fixed value but varies with ambient temperature changes.

The safe temperature for a heating element depends on its materials, construction and general design. Nickel-chromium exposed resistors can operate at temperatures up to about 2,100 degrees Fahrenheit under favorable conditions, but lower temperatures mean longer life. Carbon and graphite resistors can be operated at more than 3,000 degrees Fahrenheit when surrounded by an inert atmosphere to prevent their gradual oxidation.

When nickel-chromium resistors are embedded in a dense compressed refractory and enclosed by a metallic sheath this sheath becomes the heat dissipating surface. The manufacturers usually specify the safe maximum sheath temperature, which depends on materials, resistor design, and the gradient introduced by the refractory between the resistor and the sheath. For special alloy sheaths a maximum temperature of 1,500 degrees Fahrenheit is usually specified and 750 degrees Fahrenheit for plain steel sheaths.

Different types of heaters have quite different maximum safe-temperature limits but for many processes this maximum heater temperature can not be used because of work temperature limitations.

The selection of a proper watt density for a given heating job is one of the most difficult problems in electric heat engineering. There is no fixed ratio between the surface temperature of an electric heater and its watt density except under exactly identical operating conditions.

Each material being heated has its own critical temperature, and its own maximum rate for satisfactory heat absorption. These factors govern the selection of the permissible surface temperature in actual contact with the work. After determining the safe surface temperature for a given process the proper watt density per unit of heating surface can be computed.

The permissible watt density depends on the capacity of the work material to absorb heat. It also depends on the critical temperature of the material being heated. For instance, molasses can not be heated with as high watt density as water and even water varies according to its content of lime or other substances.

Values of watt densities frequently used in practice are given in Table I, with a distinct warning that the figures are valid only when used in a heat application having a correct over-all design. As isolated values they are worthless.

There are countless other heater applications too special to be included in even so tentative a tabulation as Table I.

The problems of automatic control for electric heat are very important but are too complex for adequate treatment here. Industrial heaters require control from two angles, first, safety for the equipment and, second, regulation of heat input to the needs of the process. For safety, the maximum temperature must be limited by automatic cutouts located at key places.

For heat input control, the proper type depends on the process and its operating conditions. Where large thermal storage capacity exists, and the rate of temperature change is gradual, as in fluid tanks, a simple on-and-off control may be sufficient. This can be supplemented by manual heat steps to take care of great variations in demand, as, for instance, in summer and winter service or in standby and operating conditions.

In other cases, close temperature regulation is necessary with rapid variations in heat demand. This calls for a more elaborate type of control, and close coordination between heater design and control selection is essential.

Where the over-all heater design permits cutting out sections of the heaters without interfering with proper heat distribution or unbalance of phase loads, the use of step controllers is satisfactory for many installations where a limited number of fixed steps of heat input are adequate.

Table I. Typical Watt Densities of Electric Heaters

Type of Service	Watts Per Square Inch of Surface	Remarks
Furnaces: nickel-chromium exposed resistors	10–20	Depends on operating temperature
Furnaces: carbon or graphite resistors in an inert atmosphere	80–120	Depends on operating temperature
Radiation heaters: nickel-chrome exposed resistors	25–40	Depends on operating temperature
High-velocity industrial air heaters	15–30	Depends on air velocity and temperature
Fan circulation unit air heaters and duct heaters	15–20	Depends on air velocity and temperature
Water heaters	20–45	Depends on water analysis and temperature
Steam boilers	10–20	Depends on water analysis and temperature
Dowtherm boilers	7–12	Depends on liquid temperature
Circulating oils, 100–200 degrees Fahrenheit	9–12	Depends on type of oil, velocity, temperature, and flow design
Circulating oils, 250–600 degrees Fahrenheit	6–9	Depends on type of oil, velocity, temperature, and flow design
Convection heating, pitch and compounds	1–3	Depends on material temperature and design details

For more critical jobs requiring extreme variation in heat input, other types of control are available. One of these is by time cycling, whereby the power is cut on and off in the proper time intervals to maintain the correct average rate of heat input. Another method is by voltage-changing apparatus utilizing variable reactors or other means of electrical impedance. This is very sensitive as the heat energy of an electric heater varies as the square of the voltage changes.

Each of the control methods described has definite advantages and disadvantages. Only careful analysis of each electric heating process can determine the most satisfactory and economical type of control. Under most conditions the cost will increase in the order in which the types of control are listed below, but so many variables affect costs that no fixed rules can apply.

1. On-and-off control—one step.
2. Multiple step control of heater sections.
3. Time cycling control.
4. Voltage changing control.

Some concrete examples of how electric heat can be profitably used for industrial process work are given in the following.

Vaporizing Dowtherm

Dowtherm is a useful heat transfer medium whereby vapor can be utilized at high temperature with far lower pressure than for steam of equal temperature. As an example, Dowtherm *A* vapor has a pressure of only 88 pounds per square inch gauge at 700 degrees Fahrenheit.

For vaporizing Dowtherm in moderate or small-sized units, electric heat is very satisfactory. A suitable pressure vessel with submerged tubes enclosing electric heaters can be constructed with all welded joints, for containing the fluid. Explosionproof terminal boxes on the heater tubes, and explosionproof controls make such a vaporizer safe for locations convenient to the work without hazard from inflammable vapors.

Hot Oil Heat Transfer

For temperatures up to 600 degrees Fahrenheit, hot oil can be recirculated by a suitable pump through an electric oil heater and a jacketed vessel or work kettle, at very low pressures. Usually not over 20 pounds per square inch gauge is required to maintain circulation at the proper velocity for correct heat transfer.

Systems of this kind in units of from 50 to 300 kw capacity are successfully used in many chemical processes. Such heaters are compact, well insulated, safe for hazardous locations and when properly designed with correct oil flow velocity, heat density, and automatic control, give years of reliable operation without interruption of service. They can be located close to the work.

Superheating Steam

Where moderate quantities of steam must be superheated electric heat can be applied so as to maintain very close temperature tolerances even with a great variation in volume of steam flow. The low British-thermal-unit input per pound of steam per degree of superheat makes this a critical design problem which can best be solved with electric heat and special sensitive controls.

Surface Heating of Materials

Infrared heat can be radiated and reflected to the surface of materials such as plastic sheets, fabrics, paper, metals, glass, and so forth, as they pass under, over, or between high-temperature electric resistance radiant heaters without actual contact with them.

Heavy duty heaters of this type can be built into kilns, conveyors, dryers, presses, rolls and machines of all kinds. They are compact, very rugged and safe for all commercial power services up to 600 volts.

It is impossible to make general comparisons between the operating cost of electric heat and fuel fired equipment. Only in a specific case can the many variable factors be evaluated. Due to thermal losses in converting fuel into electric power, electricity can never compete with fuel for general heating purposes but there is no direct ratio between fuel cost and electric heat cost.

Electric heat will cost more to one user than to another even in the same city, because electric power costs depend on the class of service, the demand curve and many other factors which vary greatly. Electricity can not be stored like other fuels and heavy peak loads for short periods mean added cost.

Very often electric heat actually reduces the unit cost of a manufactured product by improving quality, reducing waste, saving skilled labor, and avoiding hazards. In many processes no other fuel can produce the desired results.

The tremendous growth of electric heating in industry is proof that it has its logical place along with fuels. The heavy load must always fall on fuels, but, with more careful engineering analysis of industrial heating problems, an increasing number of logical uses for electric heating will be found. The future of electric heating will not depend on its cost relation to fuels but rather upon how well the responsible engineer analyzes and solves the intricate design problems incident to the full utilization of its inherent possibilities.

No Discussion

Irrigation Pumping with Grand Coulee Power

S. M. DENTON
ASSOCIATE AIEE

CENTRAL Washington is one of the few areas in the semiarid western states where the quantity of water flowing in the streams is more than sufficient to irrigate all the suitable arable land in the area. The Columbia river is characterized by high summer flow coexistent with the irrigation season.

The purposes of the Columbia Basin Project are irrigation of land, power development, and to a minor extent flood control and improved navigation. In its most compact form, the final plan for the development of the Columbia Basin comprises

1. The world's largest concrete dam (Grand Coulee Dam).
2. A reservoir (Franklin D. Roosevelt Lake), extending 151 miles to the Canadian boundary.
3. Two powerhouses, which will, when completed form a concentration of power greater than any in existence today.
4. Two interconnected switchyards.
5. The world's largest pumping plant.
6. An equalizing reservoir.
7. An extensive system of canals, tunnels, siphons, wasteways, control works, and miscellaneous appurtenances sufficient to irrigate about 1,000,000 acres of land in an area 60 miles wide and 80 miles long.

As the land to be irrigated lies on a plateau several hundred feet above the level of the Columbia river reservoir, water is to be pumped from the Columbia river reservoir to a reservoir formed by damming the two ends of the famous Grand Coulee, a remarkable prehistoric erosion channel cut to a depth of several hundred feet and from two to five miles wide through a 30 mile stretch of lava plateau. To serve the full Columbia Basin area, it will be necessary to raise a huge flow of water, about 16,000 cubic feet per second, through a lift ranging up to 365 feet. The power required for this work amounts to nearly a million horsepower.

Pumping Plant

The pumping plant will be located just upstream of the west abutment of the Grand Coulee dam and will contain an ultimate installation of twelve pumping units. The foundation for the pumping plant is a part of a wing dam which intersects and forms an angle of 67 degrees with the main dam. This part of the pumping plant structure has been completed. The pumping plant superstructure is expected to be completed in time to start the pumping of water early in 1951. The pumping plant structure will house the pumping units and pertinent controls.

The operation of ten pumping units will be required to meet maximum pumping requirements under the fully developed irrigation plan. Space has been allowed in the pumping plant building for the ultimate installation of 12 pumping units of which two are spare units. Standby units may be needed in the event of required maintenance on any component part of the generator-pump motor combination. Six pumping units will be installed initially with the first two scheduled for operation early in 1951.

To prevent pumped water from the balancing reservoir from flowing back through the pumps, the pump discharge line is designed with a siphon discharge outlet equipped with an air brake which will function when action is initiated by pump stoppage. When the pumping units are stopped by power failure or from other causes, the water in the discharge lines will return through the pumps and cause the pumping units to rotate in the reverse direction. Under conditions of maximum head, the pumping units may approach the maximum overspeed for which they have been designed.

A generator voltage bus structure will deliver power from the 108,000-kva generating units to the pump motors and will traverse the downstream slope of the Grand Coulee dam and occupy one of the galleries in the pumping plant building.

Pumps

Pumps of unprecedented size are being built for this installation. Each pump will lift 1,350 cubic feet of water per second its rated head of 310 feet from Roosevelt Lake to a canal feeding the balancing reservoir in the Grand Coulee. The pumps will operate through the pumping lift range of from 270 feet to 365 feet. The greater portion of the pumping will be through a lift of 270 feet when the reservoir is full. Under this condition the pumps will deliver in excess of 1,600 cubic feet per second. Varying river conditions cause the level of the reservoir to fluctuate as much as 95 feet. The pumps with intakes in the reservoir are placed below the lowest water level so that they will always operate under a positive pressure and avoid the risk of cavitation that is present when negative pressures occur. The size of these pumping units is indicated by the size of the pump impeller which is a steel casting fourteen feet in diameter. The impeller will be mounted on a 27-inch shaft for connection to the driving motor. Each pump will weigh approximately 500,000 pounds with the weight of the revolving parts about 120,000 pounds. Each pump will be supplied by an intake or suction tube fourteen feet in diameter which may be closed

Paper 48-192, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24–27, 1948. Manuscript submitted June 11, 1948; made available for printing July 16, 1948.

S. M. Denton is with the Bureau of Reclamation, United States Department of the Interior, Denver, Colo.

Figure 1. Torque requirements of motors

Figure 2. Deceleration curve of generating unit

off at the intake by a roller gate 13 feet by 20 feet in size. The discharge pipe from each pump is constructed of steel plate and is twelve feet in diameter. The discharge pipes are about 700 feet long and will be encased in concrete within a tunnel cut in the rock for approximately the lower two-thirds of the length of the pipe.

Power Plant

Eighteen main generating units comprise the ultimate installation at Grand Coulee power plant which is divided into two powerhouses, one located at each end of the dam. The generating units are each capable of carrying up to 130,000 kw under favorable hydraulic conditions. The dam, reservoir, and one powerhouse are substantially complete, and power has been produced since March 1941. Nine 108,000-kva generating units have been installed in the left powerhouse and are now in operation. The building for the right powerhouse is partially complete and will be ready to accommodate the installation of nine generating units which are scheduled for operation, three units each in 1949, 1950, and 1951.

Since the beginning of its operations in 1941, the power plant at Grand Coulee dam has carried a heavy load throughout the year and has been loaded to capacity almost continuously due to heavy demands from members of the Northwest Power Pool, a pool originally formed as a war measure to include the public and private utility systems in Washington, Oregon, Idaho, Montana, and Utah.

Description of Generating Units

The hydraulic turbine-driven generating units at Grand Coulee are the largest in existence. Six of the nine units now in operation will supply power for operation of the pumping plant. Each generator is direct-connected to a vertical shaft hydraulic turbine rated 150,000-horsepower at 330-foot hydraulic head and 120 rpm. The generators are rated at 108,000 kva, unit power factor, 3-phase 60-cycle and 13,800 volts. The normal excitation voltage is 250 volts. The generators to be used to furnish power for pumping have separate motor generator exciter sets to provide excitation during the reduced speed starting of the pump motors.

Generator characteristics influencing the pump motor design include the following:

Direct-axis transient reactance, 22.8 per cent.

Direct-axis subtransient reactance, 16.1 per cent.

Direct-axis transient short circuit time constant, 1.9 seconds.

Direct-axis transient open circuit time constant, approximately 8.66 seconds.

Direct-axis subtransient time constant, 0.54 seconds.

Armature resistance, 0.003651 ohms.

The combined turbine and generator WR^2 is 178,500,000 pound feet squared.

Design Features of Motors

Motors to drive the 1600-cubic feet per second pumps are of the synchronous type, each rated 65,000 horsepower at 200 rpm. They will operate at 13,600 volts, unity power factor, 3-phase 60-cycle, alternating current, and will be generally in accordance with the latest requirements of the American Standards Association. The motors are designed to rotate counterclockwise and to withstand the stresses resulting from operation at runaway speed of 295 rpm in either direction. The motors are of the vertical type with the thrust bearing located above the rotor supporting the rotating parts of the motor and pump. The weight of each pump runner and shaft and the unbalanced hydraulic thrust will be about 250,000 pounds. The weight of a complete pump motor is approximately 700,000 pounds, and the weight of the rotating parts will be in excess of 300,000 pounds. Each thrust bearing is equipped for establishing and maintaining an oil film during the starting cycle and until sufficient speed is attained to insure a full thickness of oil film. Each motor will have a separate motor-generator exciter set to furnish excitation during the starting operation. An enclosed cooling system is furnished with each motor.

In addition to motor breakaway torque, 30,000 pound feet is required to be developed by each motor to be applied to the breakaway of the pumps. The torques to be developed by each motor being accelerated through any speed will exceed that indicated by the speed torque curve shown on Figure 1. The WR^2 of the pump operating at 200 rpm with the pump casing full of water is 1,900,000 pound feet squared. The torques available for synchronizing one motor when connected singly to a generating unit at 45 per cent of normal speed and below, and at

Figure 3. Estimated possible performance of pump motors and generating units

Figure 4. Diagram of pumping arrangement

35 per cent and below when two motors are connected to one generating unit, will exceed the torque requirement indicated by the speed torque curve. The pullout torque for each motor at normal voltage and speed is standard for a motor of this rating and will be not less than 150 per cent of full load torque.

Starting Methods for Motors

The unprecedented size of the pumps and motors also presented a new field of problems. Considerable study of these problems was required preliminary to issuance of specifications for the motors and generators. Consideration was given to the use of 60-cycle reduced voltage starting, but this method involved excessively high currents and high stresses in the windings of the connected machines. Therefore this method was discarded in favor of a scheme whereby one or both of a pair of pump motors will be started by a single generating unit at less than normal voltage and frequency. During normal operation, two motor-driven pumps will be connected directly to one generating unit through a generator volt-

Figure 5. Generating unit with direct-connected exciters for commercial operation

age bus. The bus will be of the air insulated metal enclosed type with each conductor in a separate nonmagnetic housing. The longest of the bus structures will be about 1,700 feet, and the average length will be about 1,200 feet.

Two methods of starting have been considered in the designs of these motors.

1. The synchronous method in which motors are direct connected to the generators at standstill and brought up to normal speed in synchronism.

2. Starting as an induction motor with generating units operating at reduced speed when the motors are pulled into step.

It is planned to use the synchronous method exclusively unless operating conditions develop which would necessitate shorter starting operations. The synchronous method of starting will result in less shock to the generating and pumping units.

Synchronous Method

When the synchronous method of starting is used, one or two pump motors will be connected to one generator at standstill. The proper setting will be arranged for the generator and pump motor exciter field rheostats. Excitation will be applied to both the generator and pump motor fields simultaneously with the opening of the turbine gates. Adjustments can be made as desired in the field rheostats as the turbines start and accelerate. However, this will not be necessary under normal operating conditions. The generating unit and the pumping unit or units will be accelerated to normal 60-cycle speed by operation of the governor gate control causing the gates to open. At normal 60-cycle speed, the units will be placed under the control of the hydraulic governor. Starting and breakaway torque for both the motor and pump can be provided with this method of starting. The motors being furnished will have maximum starting torque above actual requirements to allow some variations from optimum starting conditions. The resistance of the armature circuits for both generator and motors plus the connecting bus is less than $1^1/_2$ per cent on the generator base. Higher resistance in the armature circuits would reduce the amount of starting torque available, and considerably higher resistance in the armature circuits might make this method of starting impractical.

The motor designs also allow for some variations in the strength of the generator and motor fields. The relative strength of the generator should normally be greater than that of the motor for optimum conditions. The ratio of the motor excitation to the generator excitation varies from approximately 0.6 to 1.0.

The measure of relative field strength is compared on the basis of open circuit voltages. The optimum starting torque condition will be obtained with a ratio of relative motor field strength to the relative generator field strength of approximately 0.8.

An optimum rate of gate opening is anticipated for the turbine driving the generator in the generator-motor combination. Gate openings faster than the optimum are expected to approach a rate at which the motors will be unable to follow. On the other hand, a rate of gate opening which is slower than the optimum is expected to have little adverse affect on starting operations.

Induction Motor Method

When induction motor starting is used, the speed of the generating units will be reduced to about 65 per cent of normal for starting one motor or 70 per cent for starting two motors. The fields of the motors and the generator will be unexcited. One or two pump motors will be connected to the generator by means of the generator voltage bus structure. With the generating unit rotating at the reduced speed, excitation will be applied to the generator field causing the motors to start as induction motors, to accelerate, and to pull into step with the generators at a decelerating generator speed. The generator and pump motor exciter field rheostats will be adjusted before starting to a setting which will be the most suitable to cover the entire starting and accelerating period. However, the generator exciter field rheostat may be adjusted during the starting operation to obtain improved starting conditions as the motors start and accelerate. The turbine gates will remain closed during the initial starting period. The load of the motor or motors starting will reduce the speed of the generators as the stored energy in the generating unit is transferred to the pumping units and as the motors start and accelerate. The motors and the generator to which they are connected will drift toward a common electrical speed and when sufficiently close, the motors and generator will be pulled into step by application of the motor field. The motor field excitation will be applied at or near the most favorable angle between the motors and generators. After the motors and generator are

Figure 6. Pumping plant site before completion of the dam showing tunnels for pump discharge pipes

Figure 7. Pumping plant foundation on wing dam shown in foreground

Figure 8. Section through proposed pumping plant

synchronized, the turbine gates will be opened to bring the generator motor or motors to normal speed. At normal 60-cycle speed the units will be placed under the control of the hydraulic governor.

The generator performance for this method may be approximated by using its zero power factor volt-ampere curve. This approximation is obtained by plotting the current which the motor or motors will draw at rated voltages on the same chart with the zero power factor volt-ampere curve of the generator. A line drawn from this point to the origin intersects the volt-ampere curve of the generator and gives current and voltage values which the generator can deliver. These values are conservative, however, since the power factor will actually be better than zero. The torque available would be reduced below rated torque by the ratio of the square of the reduced voltage to the square of the rated voltage of the motors. Figure 2 shows the average deceleration for the generating units which will be used for pumping. It is possible to estimate the action of the generator and its connected motor or motors when starting under the induction motor method. When starting one or two motors, the motors and generating unit may be expected to approximate the general type of performance indicated on Figure 3. Initial generating unit speeds for this method of starting may be less than those mentioned above and as shown on the curves. The minimum starting speed for the generating unit can be determined best by test as well as the most favorable speed for starting either one or two motors.

Operating Conditions

The output of a generating unit may vary from about 80,000 kw to 130,000 kw or more depending upon the amount of head available on the turbine. One or two pumps may be driven from one generating unit depending upon the pumping requirements and capabilities of the generating unit. Excess generating capacity over the normal rated loading of the pumps may be used by increasing the speed above the normal rated speed of the pumping units. The pumping units will be loaded approximately as the cube of the operating speed.

The generators assigned to irrigation

Figure 9. Irrigation system for Columbia Basin Project

pumping will be available for commercial service during the nonirrigation periods. By resorting to intermittent pumping, the generators assigned to irrigation pumping may also be used to meet daily peak demands even at the height of the irrigating season. The general plan for pump operation will be integrated in so far as possible with the commercial power requirements for the Grand Coulee power plant so that little or no interference will result in the power demands being met.

Discussion

M. R. Lory (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Denton has given a very interesting description of this outstanding engineering project of which almost every part is the largest of its kind. The pump motors are the most powerful ever built by a wide margin.

The problem of starting these large motors is one of the most interesting to engineers. Although there is no previous experience in starting motors of this size, we are still close enough to similar practices so that successful performance is assured. The synchronous starting of large machines is commonly done on the test floor of all manufacturers of electrical equipment. The largest generators are started by this method, using a driving generator much smaller in relation to the machine being started than will be the case at Grand Coulee.

The induction motor method of starting is exactly like the method used to maneuver the propeller in modern a-c ship propulsion installations. On shipboard, we have a generator equal in rating to the motor it drives. The maneuvering is done at reduced generator speed, with the motor acting as an induction motor until the motor approaches synchronous speed. On many twin-screw vessels we have the case of two motors being started from one generator. In these ship drives, tests check calculated performance closely and the same should hold true for the Grand Coulee motors.

Out of the six motors in the initial pumping installation, four are being furnished by the Westinghouse Electric Corporation. These machines are 31 feet, 3 inches, in diameter over the air housing, and extend 18 feet, 3 inches above the pump room floor. The total over-all height from the face of the shaft flange to the top of the tachometer housing is 24 feet, 2 inches. The total weight of each motor is 690,000 pounds, and the rotor weighs 348,500 pounds. The thrust is carried by a 56-inch diameter Kingsbury-type thrust bearing.

Because of the unprecedented size of these motors, the Bureau of Reclamation has specified many instruments and protective devices to detect abnormal conditions and give the operators complete information on operating conditions. I will not go into detail regarding all of these devices but it may be of interest to consider the instruments and devices provided for the protection of the thrust bearing.

The temperature of the oil in the thrust bearing pot is measured by a mercury thermometer and also by a remote reading, recording thermometer which keeps a continuous record. Resistance-type temperature detectors are located in two shoes of the bearing and a temperature relay also has its bulb in the metal of one bearing shoe and will sound an alarm if the temperature becomes excessive. The temperature of the cooling water for the bearings is measured by mercury thermometers in the inlet and outlet, and a pressure gage is located in the supply line. Failure of the cooling water is detected immediately by a pressure failure relay in the cooling water supply header.

Denton mentions that a means is provided to establish the oil film in the thrust bearing before starting the motors. This accomplishes the double purpose of reducing the starting torque, and eliminating any possibility of damaging the bearing during the first few revolutions. In the Westinghouse motors, the oil film is introduced by jacking up the rotor a short distance to permit oil to flow between the bearing surfaces, and then lowering the rotor. Jacking is done by the jacks ordinarily furnished to jack the rotor for disassembly of the thrust bearing and to brake the rotor to a stop when shutting down. However, special equipment is provided so that the operator can complete the raising and lowering operation quickly and conveniently.

To raise the rotor, the operator moves a switch at the control station to "raise." This starts the high pressure pump and at the same time, applies air pressure to the oil in the supply tank. The air pressure fills the piping with oil through a by-pass and check valve around the pump. As the jacks start to rise, a green light at the control station goes off and a red light comes on. When the jacks come in contact with the rotor, the pressure rises, and the high pressure pump lifts the rotor 1/4 inch. At this point, a limit switch shuts down the pump and lights an amber light to indicate that the lift cycle is completed.

The operator then moves the control switch to "lower," and the lowering is automatically accomplished. Air pressure above the oil in the tank is released, and a solenoid valve permits the return of the oil to the tank through a flow control which gives the proper lowering speed. When the rotor is down, the amber light goes off, and the pressure drops in the system. The drop in pressure opens a discharge valve to empty the jack cylinders quickly. When the jacks are down, the red light goes off, and the green light comes on, indicating that the motor is ready to start. At the same time, the discharge valve is closed to maintain the system full of oil.

The oil introduced between the bearing surfaces by jacking up the rotor does not squeeze out for some time. The operator can easily complete the starting cycle while the oil film is maintained. The jacks can be used for braking the rotor to a stop in the normal way except that air is not admitted directly to the cylinder but is admitted to the oil supply tank, and the pressure is transmitted to the cylinders by the oil.

These motors will not be in service for some time, but I hope that Denton or his associates will give us additional papers in the future, as the tests are made after installation and operating experience is obtained.

S. M. Denton: Lory has given some very interesting comments from the motor designer's point of view which are greatly appreciated. His discussion regarding the two starting methods relating these methods to commonly used procedures is reassuring. He also brings out some of the interesting details in the design and manufacture of motors of this size.

Development of the 230-Kv Ring Bus for Grand Coulee Power Plant

N. G. HOLMDAHL

C. L. KILLGORE
MEMBER AIEE

GRAND COULEE power plant at Coulee Dam, Washington, is the largest hydroelectric power development in the world and, when completed, will have an installed capacity of over 2,300,000 kw. This unprecedented concentration of generating capacity presented a real and worthwhile problem in the selection, design, and development of the most desirable bussing arrangement and was first presented in an earlier paper[1] by Hoard and Bills. This paper discusses the problems of determining the ultimate bussing arrangement for Grand Coulee power plant and presents the reasons for the final selection of a 230-kv ring bus.

Most present-day high-voltage transmission systems in this country use a solid bus arrangement, or slight variations from it, because of the availability of quick-clearing high-interrupting capacity circuit breakers. In fact the need for this type of bus arrangement has resulted in the continued development of high-voltage circuit breakers of increasing interrupting capacity. For all but the larger generating stations, presently available 230-kv circuit-breaker interrupting capacities of 3,500,000 kva permit the use of a solidly-connected high-voltage bus arrangement which gives a high degree of stability and operating flexibility. However, in the case of Grand Coulee power plant circuit breaker interrupting capacities of 3,500,000 kva were not sufficient to permit the use of a solid high-voltage bus. Two opposite approaches appeared feasible.

1. Reduce the magnitude of the short-circuit by bus sectionalizing or the use of bus-tie reactance.
2. Increase the circuit breaker interrupting capacity.

The final solution of this problem required extensive work on the network analyzer, design studies and cost analysis as well as field tests[2,3,4] at Coulee Dam to determine the maximum interrupting capacity 230-kv oil circuit breakers that could be developed at this time. The following four factors, were given major consideration in determining the ultimate bussing arrangement for Grand Coulee power plant.

1. Circuit breaker interrupting capacity.
2. System stability and relaying.
3. Simplicity and operating flexibility.
4. Cost.

Grand Coulee Power Plant

Grand Coulee power plant is located on the Columbia River approximately 90 miles west of the city of Spokane near the center of the state of Washington. The power plant is also near the electrical center of the Northwest Power Pool, which has a peaking capacity of over 3,500,000 kva, and extends over the states of Washington, Oregon, Idaho, Montana and Utah. Grand Coulee power plant is connected to the Northwest Power Pool through the transmission facilities of the Bonneville Power Administration and the development of this transmission system is described in a companion paper[5] by Hoard and Helwith.

The Grand Coulee power plant was designed, constructed and is operated by the United States Bureau of Reclamation as an integral part of its Columbia Basin Project. This is a multipurpose project which will eventually irrigate over 1,000,000 acres of land in central Washington, and have an installed hydroelectric generating capacity of over 2,000,000 kw. Grand Coulee consists of two power plants located on either side of the Columbia River as shown in Figure 1. Each power plant will ultimately contain nine of the world's largest hydroelectric generators,[6] shown in Figure 2, each having a nameplate rating of 108,000 kw with an actual peaking capability of 130,000 kw. At present all nine of the generators are installed in the left power plant, as shown in Figure 3. The nine generators for the right power plant are scheduled to be in operation by 1952.

A unit-system consisting of a generator and its associated transformer bank wherein all bussing is accomplished on the high-voltage side of the transformer banks at the 230- and 115-kv switchyards is used at Grand Coulee. Seven of the generators in the left power plant supply power at 230-kv, one generator supplies power at 115-kv and one generator is connected to a 3-winding transformer with full capacity 115- and 230-kv high-voltage windings. This bank serves as a tie between the 115- and 230-kv switchyards. All nine of the generators in the right power plant will supply power to the 230-kv system.

Irrigation Pumping Requirements

The Grand Coulee pumping plant, now under construction, is located adjacent to the dam and will ultimately contain twelve 1,600-cubic feet per second 65,000-horsepower irrigation pumps[7] which will lift the waters of Lake Roosevelt 295 feet to an irrigation system in the Columbia Basin. Six of the nine generating units in the left power plant are arranged to either drive the twelve pump

Paper 48-193, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE Pacific general meeting, Spokane, Wash., August 24-27, 1948. Manuscript submitted June 18, 1948; made available for printing July 22, 1948.

N. G. HOLMDAHL is with the United States Bureau of Reclamation at Coulee Dam, Wash., and C. L. KILLGORE is with the Bureau at Denver, Colo.

The authors wish to acknowledge the excellent cooperation and assistance of the engineers of the Bonneville Power Administration, the General Electric Company and the Westinghouse Electric Corporation, in developing the 230-kv ring bus for Grand Coulee power plant. Without the vision of the manufacturers' engineers in undertaking the development of 10,000,000-kva 230-kv circuit breakers, the 230-kv solid-ring bus at Coulee Dam could not have become a reality.

Figure 1. Grand Coulee Dam and power plants, with 230-kv left switchyard in right background

motors or to supply commercial power. Each of the six generating units will operate two pumping units through a generator-voltage bus between the power plant and the pumping plant.

The irrigation season, which begins gradually in the spring, reaches a peak in mid-summer, and tapers off until completion in the fall, also occurs when the maximum secondary power is available for irrigation pumping, since this is the high water flow season in the Columbia River and the requirement for commercial power is less than during the winter months. Considerable water storage will be provided in the irrigation canal system so that irrigation pumping can normally be scheduled during off-peak load periods. However even with maximum available secondary power and off-peak pumping it must be possible to continue to supply all or part of the commercial load which is normally assigned to any generating units being used for irrigation pumping, and any bussing arrangement selected for Grand Coulee power plant must provide for this fundamental operating flexibility.

Bussing Arrangements

Four basic bussing arrangements were considered for Grand Coulee power plant.

1. Isolated units and lines.
2. Multiple-winding transformers.
3. Interleaved transmission lines.
4. 230-kv reactor and solid ring bus.

Isolated Units and Lines. Since 2,500,000 kva was the highest interrupting capacity, 230-kv oil circuit breakers available at the time the power plant was originally designed, it was necessary to adopt a bussing arrangement using isolated units and lines in order to limit the circuit breaker duty. This scheme consisted of a complete 230-kv double bus with two generators and two transmission lines isolated on a single bus section. The economical utilization of power with this scheme depended upon sufficient interconnections between load centers so that all generators could be fully loaded regardless of the system load distribution. As the transmission system developed, it soon became evident that this condition would not be realized and the isolated unit and line bussing arrangement was abandoned.

Multiple-Winding Transformers. With circuit-breaker interrupting capacity still considered a limiting factor, various bussing arrangements using multiple-winding transformers were studied. These schemes are discussed in a paper[8] by Bills and MacArthur, and are essentially a ring bus with the interconnection between bus sections being established through the transformer windings which provide a means for transferring power and maintaining synchronizing torque between bus sections. While the reactance of the transformer windings limits circuit breaker duty, it also limits the amount of power that can be transferred between bus sections. Further investigation of this scheme indicated that it would

Figure 4. Schematic diagram of split bus arrangement for Grand Coulee power plant with interleaved line connections to transmission system of Bonneville Power Administration

be difficult to obtain the desired reactance between all transformer windings, that installation of large multiple-winding transformers in the existing power plant would be difficult, and that the cost of such an installation would be high. In view of these facts and the limitation in operating flexibility imposed by the necessity of transferring power through multiple-winding transformers this scheme was discarded.

Interleaved Transmission Lines. When higher interrupting capacity circuit breakers became available the existing line circuit breakers at Grand Coulee power plant were rebuilt from 2,500,000 to 3,500,000 kva. However, with the installation of only four of the ultimate 18 generators and three transmission lines, this interrupting capacity was exceeded. In order to limit circuit breaker duty, a bussing arrangement having two isolated bus sections with interleaved transmission lines between the nearest substations was adopted for Grand Coulee power plant. A simplified schematic diagram of this bussing arrangement is shown in Figure 4. It will be noted that two parallel transmission lines are installed between Grand Coulee power plant and each substation on the transmission system. One transmission line of each pair of parallel lines is connected to each bus section at Grand Coulee and the lines are connected together at the substations. Half the generation at Grand Coulee is connected to each bus section and synchronizing power between the two bus sections flows through the interleaved transmission lines and substation busses with line reactance limiting circuit breaker duty.

This bussing arrangement seriously limits system operating flexibility since power cannot readily be transferred from one load area to another except through the interleaved transmission lines, and it is impossible to predict line loadings for various loads in the different areas on the system. In case of a system disturbance even with only six generators and six lines in service, the operators have difficulty in determining what has occurred or how the line loadings will redistribute. In addition, line relaying problems are greater with interleaved lines, particularly in regard to induced voltages in the parallel lines. Because of these limitations in operating flexibility the interleaved transmission line bussing arrangement was also abandoned. Six of the existing circuit breakers at Grand Coulee power plant have been rebuilt to 7,500,000 kva to permit changing over from the interleaved scheme to a solid bussing arrangement for the left power plant and 230-kv switchyard by the fall of 1948. This interim scheme of operation with eight generators and six transmission lines solidly connected together was necessary to provide sufficient operating flexibility to supply the changing load areas and will be used until the 230-kv ring bus is installed in 1949.

230-Kv Reactor and Solid Ring Bus. Figure 5 shows a simplified schematic diagram of the 230-kv ring bus which was finally selected as the ultimate bussing arrangement for Grand Coulee power plant since it offered the greatest advantages of any scheme considered. Essentially, the ring bus scheme consists of connecting the main busses in the 230-kv left and right switchyards together with two tie circuits crossing the Columbia River to form a closed ring to which all generators and lines are connected. The ring bus is divided into five sections through a bus-tie circuit breaker with each section containing three generators and two transmission lines so that in case of a bus fault only 20 per cent of the generation and line capacity is lost.

With a 230-kv ring bus arrangement the output of Grand Coulee power plant will automatically be transmitted to the load areas where it is most needed up to the capability of the outgoing transmission lines. Power can be transmitted in on some lines and out on others if an excess of generation exists in one area and there is a shortage of power in another. During the irrigation season when a maximum of five generators are being used for irrigation pumping and are off the commercial system power can be routed around the ring to the bus sections and their associated transmission lines from which the generators have been removed for irrigation pumping. A 230-kv ring bus appears to be particularly well adapted to the condition of operation at Grand Coulee power plant, and although it requires somewhat more initial capital investment, the advantages of greater operating flexibility and ease of maintenance are considered to more than offset the additional first cost. Variations of the 230-kv ring bus which were considered are as follows

1. A solid ring bus.
2. A ring bus with three 230-kv reactors to limit circuit breaker interrupting ca-

Figure 5. Schematic diagram of 230-kv ring bus for Grand Coulee power plant with parallel line connections to transmission system of Bonneville Power Administration

pacity and possibly increase system stability.

3. A ring bus with five 230-kv reactors located adjacent to each bus-tie circuit breaker.

Since 230-kv reactors are relatively expensive and constitute a limitation in the amount of power that can be transferred around the ring bus, it was decided to consider a solid ring bus which meant that 230-kv circuit breakers with much higher interrupting capacity than the presently available 3,500,000 kva would be required.

Circuit Breaker Interrupting Capacity

With all generators, pumps, and lines in operation, calculations indicate that it ultimately will be theoretically possible to obtain a maximum 3-phase fault of approximately 12,000,000 kva on a transmission line adjacent to the 230-kv switchyard bus.

Decrement Curves. The Grand Coulee generators have a low subtransient reactance of 16 per cent and, therefore, contribute a considerable d-c component to the total fault current for faults close to the 230-kv switchyard. Figure 6 shows the ratio of total rms current in per unit of initial symmetrical 3-phase short-circuit current from actual field tests to be approximately 1.4 for faults supplied entirely by the generators without any feedback from transmission lines, while the ratio with an equal number of generators and transmission lines is 1.2. The circuit breaker contacts are assumed to part at 2.25 cycles after the fault is initiated. An average ratio of 1.35 was used for the ultimate installation.

Pumps Isolated. To avoid increasing the interrupting duty on the generator-voltage circuit breakers used for the pump motors it was decided that the irrigation pump motors and their associated generators would not be operated in parallel with the commercial power system. However, each pair of pumps, when operating at rated speed and head, will not require the full capacity of their associated generators, and in order to utilize the available generator output it is planned to operate the pumps and generators at about 109 per cent rated speed. Under conditions of normal tailwater and maximum lake elevation it is expected that nearly 1,900 cubic feet per second will be obtained from each pump.

Circuit Breaker Interrupting Capacity. It was believed that the highest interrupting capacity 230-kv circuit breakers which it was possible to obtain from the manufacturers should be used for the 230-kv ring bus. In order to determine the maximum possible interrupting capacity circuit breaker that could be developed at this time, it was necessary to conduct a series of field tests at Coulee Dam. In view of the very successful results of these tests as reported in previous papers[2,3,4] it was determined that 3-cycle 230-kv oil circuit breakers with 10,000,000-kva interrupting capacity could be built for the Grand Coulee power plant. These circuit breakers were required also to have a continuous current carrying capacity of 1,000 amperes and to have a rating of 10,000,000-kva with one 20-cycle reclosure. Contracts have been awarded for fifteen new 230/196-kv 10,000,000-kva circuit

Figure 9. System exposure to faults from operating records for years 1945–1947

breakers and for the necessary parts to rebuild six of the existing 3,500,000-kva line circuit breakers to 10,000,000-kva interrupting capacity.

Maximum Theoretical Fault and Experience. While calculations show that it ultimately will be theoretically possible to obtain faults in excess of 10,000,000 kva, it is believed that this interrupting capacity is adequate for the ultimate installation at Grand Coulee power plant as discussed below. Operating records for Grand Coulee power plant from 1941 to 1948 show that 69 per cent of all line faults were line-to-ground, 29.9 per cent were phase-to-phase and only two or 1.1 per cent were 3-phase faults. Since line-to-ground faults with the neutrals of the transformer banks solidly grounded will increase the theoretically possible 3-phase fault of 12,000,000 kva by approximately 30 per cent, reactors will be installed in the neutrals of the transformer banks to limit the line-to-ground faults to 10,000,000 kva when increased system capacity makes this necessary. The addition of these neutral reactors will still permit the system to be classed as solidly grounded since the ratio of the zero sequence reactance X_0 to the positive sequence reactance X_1 will be less than three which will permit the application of line-to-ground rated lightning arresters. With the line-to-ground faults limited to 10,000,000 kva the following simultaneous conditions must occur to obtain a fault in excess of that value.

1. The fault must be a 3-phase fault, and must be a solid fault without any resistance.
2. The fault must be on a transmission line within a radius of about one mile from the switchyards. The bus-tie circuit breakers will never be required to open 10,000,000 kva.
3. All generators must be in operation and maximum feedback must be obtained from the transmission system. This assumes no irrigation pumping and no generators out for maintenance.
4. The fault current must be practically fully offset, which is only obtained when the fault is applied at voltage zero.

Therefore, the probability of obtaining a fault in excess of 10,000,000 kva is extremely remote and even if it did occur the bus-tie circuit breakers will provide back-up protection in case a line circuit breaker fails to clear the fault.

Experience records at Grand Coulee show that while it was theoretically possible to have a fault of 3,400,000 kva, the necessary simultaneous conditions as previously listed did not occur and, therefore, the maximum circuit breaker duty actually did not exceed 1,900,000 kva. Also the majority of the faults were less than half of the theoretically possible maximum as shown on Figure 7. Only 10 per cent of the faults were more than 50 per cent offset at zero time as shown on Figure 8. The actual system exposure to faults for the years 1945–1947 is shown on Figure 9. Circuit breaker duty decreases very rapidly with the addition of only a few miles of transmission line as shown in Figure 10. This is especially true at Grand Coulee power plant since the few extra ohms resistance associated with a few miles of transmission line results in a small (fast) d-c time constant which acts to reduce a large proportion of the fault current which comes from the generators. In addition the transmission lines radiating from Grand Coulee are protected by overhead groundwires for approximately one-half a mile from the switchyard. From the foregoing it can be concluded that for all practical purposes 10,000,000-kva interrupting capacity will be ade-

Figure 11. Physical arrangement of ultimate 230-kv main ring and auxiliary bus for Grand Coulee power plant

quate for the ultimate installation at Grand Coulee power plant, especially since it is reasonable to consider that the circuit breakers will have some margin.

Stability

The criteria for stability of the transmission system as established by the Bonneville Power Administration required that the system should be stable for a 3-phase fault at the Coulee 230-kv bus, and simultaneous loss of two parallel 230-kv transmission lines supplying the same load area. While these are rather severe stability requirements, the reasons for their selection and other aspects of system stability are fully discussed in a companion paper.[5]

However, it is desired to point out that this criteria for stability can be adequately met by a solidly-connected 230-kv ring bus, and network analyzer studies indicate that there is little difference in this stability criteria between an interleaved bus scheme, a 230-kv ring bus with low reactance between bus sections and a 230-kv solid-ring bus. For faults other than a 3-phase fault on a transmission line adjacent to the 230-kv switchyard bus the ratio of the critical switching times for the 230-kv solid-ring bus to that of the switching times for the other bussing arrangements will increase, and the 230-kv solid-ring bus results in the higher stability as the fault location moves away from the 230-kv switchyard bus. Accordingly, it can be concluded that the solidly-connected ring-bus scheme will result in greater over-all system stability for the more frequent fault conditions than that which can be obtained with an interleaved or 230-kv reactor ring-bus arrangement.

Operation and Flexibility

Since the Grand Coulee power plant is very near the electrical center of the Northwest Power Pool and is the largest single plant on the system, it is essential that the bussing arrangement be capable of providing adequate switching flexibility to route the output of the power plant to high load areas. Power may be routed by displacement through the switchyards from the coast area to eastern Washington and Montana or vice versa when power shortages occur in areas that cannot be entirely supplied by Grand Coulee.

General Operating Requirements. The general operating requirements for Grand Coulee power plant, all of which are adequately met by the 230-kv solid-ring bus, are as follows:

1. The switchyard configuration should be

such that it will be possible to transmit the total output of 17 108,000-kva generators (one spare) over ten 230-kv and five 115-kv transmission lines with the load in each line varying between zero and the maximum allowable stable loading.

2. The bussing arrangement should be capable of transferring power through the bus from a high-generation area to a high-load area up to the capability of the transmission lines.

3. A similar condition must also be met when five generators are off the system for pumping during the irrigation season and large blocks of power must be transferred from one bus section to another.

4. The bussing arrangement should be such that any piece of equipment may be removed for maintenance without impairing the power transmission capabilities.

5. The bussing arrangement should also be as simple as possible to provide ease of operation and should preferably be symmetrical.

6. The bussing arrangement should be such that the system will not lose synchronism with the simultaneous loss of two parallel transmission lines for a 3-phase fault at the 230-kv switchyard bus.

7. It must be arranged so that present available relaying equipment will provide adequate protection of the transmission lines without being unduly complicated.

Flexibility of 230-kv Solid-Ring Bus. It is evident that the greatest ease and flexibility of station and system operation will be obtained when the high-voltage bus is solidly connected.[9] For this case the power flow will be such that the load is delivered with the smallest electrical angular displacement between generator and load and the smallest amount of kilovolt-amperes for a given line capacity. System planning and development can progress naturally by strengthening the line capacity to the more heavily-loaded areas and additional capacity at the generating bus can be easily added. The increase in system kilovolt-ampere requirements following the loss of any line section is kept to a minimum as the increased loading will distribute more equally over the interconnected lines and the available synchronous capacity of the system will be better able to contribute a greater proportionate share of their available capacity. The required system synchronous condenser capacity will, therefore, be less with the solidly-connected ring bus.

Arrangement of 230-kv Ring Bus

The two power plants and their associated 230-kv switchyards for the Grand Coulee power development are located on opposite sides of the Columbia River as indicated on the single-line diagram, Figure 11. The existing 230-kv left switchyard is shown in Figure 12 and will contain 12 10,000,000-kva interrupting capacity conventional tank-type oil circuit breakers, as shown in Figure 13, in the bus-tie and line positions when the initial ring bus installation is completed. Figure 14 shows a transverse section through a 10,000,000-kva line circuit breaker position in the 230-kv right switchyard which is now under construction. This switchyard will eventually contain 9 10,000,000-kva interrupting capacity oil circuit breakers in the bus-tie and line positions. These circuit breakers will be of the low-oil content impulse-type and will be furnished complete with disconnecting switches and bushing-type current transformers as illustrated in Figure 15.

230-Kv Ring and Auxiliary Bus. Each switchyard has a 230-kv main ring bus and an auxiliary bus. The two main busses in each switchyard will be connected together by two cross-river tie circuits which will close the ring. As previously mentioned, the 230-kv main ring bus will be divided into five sections through bus-tie circuit breakers with three generators and two transmission lines connected to each bus section, except bus section number 1 which will have five generators since additional transmission lines may eventually be connected to this bus section. Space is provided at each bus-tie circuit breaker position for the future addition of 230-kv reactors if experience indicates that these are needed and they can be economically justified. A 230-kv auxiliary bus is provided for each main bus section except the cross-river tie circuits are omitted. The auxiliary bus is provided primarily for use during emergency conditions and during maintenance of the 230-kv main ring bus and its associated oil circuit breakers. The auxiliary bus is sectionalized with disconnecting-switches as shown in Figure 11 to provide the maximum operating flexibility in transferring generators from one bus section to another.

Circuit Breaker Arrangement. It will be noted from Figure 11 that double-breakers are shown in alternate line positions only, except for one pair of lines where double-breakers in both line positions were considered advisable since these lines are subject to more frequent outages than the other lines and are

Figure 12. 230-kv left switchyard

Ultimate installation will contain twelve 10,000,000-kva tank-type oil circuit breakers

Figure 13. 10,000,000-kva 3-cycle, 20-cycle reclosing conventional tank-type oil circuit-breaker for 230-kv left switchyard

Figure 14. 230-kv right switchyard

Transverse section of 10,000,000-kva line circuit breaker position

installed on double-circuit towers. Double-breakers are shown in the alternate line positions since this locates a spare breaker where it is needed most. It is well recognized that line breakers are subjected to much greater duty from interruption of line faults and line charging current than generating unit breakers which are normally subjected to only routine switching operations. The spare line breaker on the auxiliary bus can be substituted for either of the two line breakers on the main bus or for any of the three generating unit breakers on its associated bus section. Space is provided for the future installation of double-breakers in all the line positions if operating experience indicates that this is desirable.

Only single circuit breakers will be installed for each generating unit position. These circuit breakers will not require an interrupting capacity of 10,000,000 kva since it is planned to trip the bus-tie circuit breakers in case of transformer differential relay operation, which could involve a high capacity 230-kv fault, before the generating unit circuit breakers are tripped. In view of the reliability of present-day transformers tripping the bus-tie circuit breakers for the remote possibility of a transformer fault is not considered to be a disadvantage. Since faults on the low-voltage side of the transformers will be limited by the transformer reactance, an interrupting capacity of 2,500,000 kva is ample for the generating-unit oil circuit breakers. Thus, a considerable saving was made by being able to use the existing generating-unit circuit breakers for the ultimate 230-kv solid-ring bus.

Relay Protection. The relay protection scheme for a typical section of the 230-kv main ring and auxiliary bus and its associated generators, transformers, and transmission lines is shown in Figure 16. Complete overlapping differential relay protection is provided for all station equipment. The generator and transformer protection is the conventional differential relay type. The transformer differential zone on the high-voltage side extends only to the current-transformers in the high-voltage bushings which provides differential relay protection whether the transformer is connected to the 230-kv main ring bus through the generating-unit circuit breaker or to the 230-kv auxiliary bus through a disconnecting switch. The 230-kv bus differential zone extends from the transformer high-voltage bushings to each transmission line and includes the 230-kv transformer circuits and both the 230-kv main and auxiliary busses. This scheme provides complete bus differential relay protection under any

Figure 15. Drawing of 10,000,000-kva low-oil content impulse-type oil circuit breakers for 230-kv right switchyard

Figure 16. Single-line diagram of relay protective scheme for section of 230-kv main ring and auxiliary bus

switching condition by transferring trip circuits only. It will be noted that a 230-kv wound-type double-secondary current transformer is shown in the position provided for the future line circuit breakers. Installation of this current transformer permits completion of the bus and line current transformer circuits so that the normal protective relaying is always in service. With two parallel transmission lines between Grand Coulee power plant and the first substation on the transmission system the simplest type of line relaying can be used which will increase the reliability of system operations.

Conclusions

Selection of a 230-kv solid-ring bus for Grand Coulee power plant was based on the following conclusions:

1. Maximum system operating flexibility with a symmetrical switching arrangement is obtained with a 5-section 230-kv solid ring bus.

2. Maximum over-all system stability is obtained by the solid bus arrangement when using present-day high-speed circuit breakers and relays.

3. The most important means for improved performance and simplicity of bussing arrangements is the use of higher interrupting capacity circuit breakers.[10]

4. If it can be shown that installation of reactors in the 230-kv ring bus will increase the power limit of the transmission system by a sufficient amount, then it may be economically justified to install reactors.

5. However, it must be recognized that such bus-tie reactors impose a limitation on the transfer of power around the ring bus and should have as low reactance as possible and a continuous current rating ample to meet emergency conditions involving line outages.

6. By use of a ring bus additional generation and corresponding line capacity can be easily added by adding bus sections.

7. A main ring bus and a sectionalized auxiliary bus with double circuit breakers in alternate line positions provides the greatest operating flexibility and ease of maintenance at the least cost.

8. The 230-kv ring bus with two parallel lines to each load center permits the simplest type of relaying, thereby increasing the reliability of operation.

In summary it can be concluded that the 230-kv solid-ring bus which has been developed for Grand Coulee power plant will provide the required characteristics of flexibility, simplicity of operation, ease of maintenance, maximum stability, and simplicity of relaying at the most reasonable cost for operation of the largest concentration of hydroelectric generating capacity in the world.

Discussion

S. B. Crary (General Electric Company, Schenectady, N. Y.): This paper is an excellent presentation of the advantages of high-interrupting capacity circuit breakers to a major transmission system. High-interrupting capacity is a development which naturally follows quick fault clearing. The next step, already being achieved, as indicated in this paper and a paper by B. V. Hoard and E. E. Helwith,[1] is a heavier electrical loading of the transmission line circuits—all logical steps toward a more economic system.

One cannot help but be impressed by the increasing need in this country and in Europe for quick-clearing high-interrupting capacity circuit breakers. The development of such circuit breakers in this country is particularly timely as it sets a pattern, not only for American but also for European engineers just when they are planning to redesign their systems, and go to higher voltages in many cases.

These recent circuit breaker developments will provide a means for superimposing a higher voltage transmission system on an existing system of limited transmission capacity. This places the responsibility for the primary transmission on the modern higher voltage system and will allow the older lower voltage system to provide subtransmission capacity with a minimum revamping of the lower voltage system, which in many cases is inadequately designed for bulk power transmission with reliability.

S. B. Smith (Ebasco Services Incorporated, New York, N. Y.): The paper by Holmdahl and Killgore presents a 230-kv ring bus arrangement which permits flexibility not only in operation but in future transmission line connection rearrangement, when and if this is desirable. The connecting of two parallel lines to the same bus section, as set forth in their plan, does not give as great reliability of service in case of bus faults as would an interleaved scheme in which the continuous ring bus is maintained with each circuit of a pair of parallel lines connected to different bus sections.

Because of the Northwest Power Pool interconnections and the large amount of generating capacity with which Grand Coulee will normally operate in parallel, the loss of one bus section with its three connected generators at Grand Coulee could at least be partially, if not entirely, compensated for by automatically increased generation at other interconnected plants. The greatest advantage can be obtained from this relief if the various 230-kv busses throughout the interconnected power system maintain the maximum number of interties throughout the transient disturbance. This cannot be done if, for example, two parallel lines to Midway, or to Spokane, or to Snohomish are lost simultaneously when a Grand Coulee bus section trips. If an interleaved scheme were used, there would be at least one 230-kv line remaining in service between Grand Coulee and the load center busses at Spokane, Midway, and Snohomish after the loss of any one bus section at Grand Coulee. Time would be available to the system operators to order the necessary measures to correct possible overloaded lines or equipment after a bus section trips.

Line relaying problems introduced can be accepted, or additional line relaying investment can be justified in order to obtain the increased reliability of service of a ring bus with interleaved line connections.

Alexander Dovjikov (Bonneville Power Administration, Portland, Oreg.): Instead of calling the use of bus-tie reactance on one hand and the increase of circuit breaker interrupting capacity on the other as two opposite approaches, I would consider them supplementary. Everyone agrees that a solid ring bus (sectionalized by circuit breakers) is the most convenient scheme and its use for large generating power house depends upon the maximum interrupting capacities of circuit breaker available for the interruption of maximum short circuits. At the present time the manufacturing companies have agreed to build circuit breakers rated at 10,000,000 kva interrupting capacity. Insofar as calculations indicate short circuits on the bus of the fully developed system may exceed 10,000,000 kva, a place is wisely provided for the reactors in the bus described in the paper, and inasmuch as the ultimate development of the system is several years ahead, time is available to observe in actual operation the factors affecting the maximum value of the current to be interrupted and to decide upon the measures (if any) that may be necessary to decrease system fault currents to a degree commensurate with reliable operation of the circuit breakers without excessive maintenance. Whether it should be done by insertion of reactance in the neutral of the transformer or by use of bus reactors will be determined by accumulated experience and the crystallization of ideas in regard to the decrease of insulation level.

I would also like to state that the criteria for stability of the transmission system, "that the system should be stable for a 3-phase fault at the Coulee 230-kv bus and simultaneous loss of two parallel 230-kv transmission lines supplying the same load area," refers to the time when, to canalize the full output generated at Grand Coulee, the number of circuits in the 230-kv network will be sufficiently large to keep the system stable, even in such a case. Unfortunately, at the present time, the transmission system of the BPA is yet not developed to such an extent and faults accompanied by loss of the two circuits leading to the same load, as demonstrated by our recent experiences, produce dynamic instability of the system.

Martin J. Lantz (Bonneville Power Administration, Portland, Oreg.): This paper, together with the paper by B. V. Hoard and E. E. Helwith, presents two plans for the ultimate development of the Grand Coulee power plant. The plans for the future development of the power plant are progressing in the physical plant layout, so that either scheme may be adopted as the future system expands.

One major problem in the future development of Grand Coulee is the present inability to secure oil circuit breakers of sufficient interrupting capacity to meet the short circuit duties anticipated by the solid-bus scheme without bus reactors.

Preliminary calculations for a 3-phase fault on the Coulee bus for the contemplated 1956 system result in a symmetrical fault value of 12,000,000 kva. This system includes the ultimate Coulee development with 5,000,000 kva of the fault coming from the system exclusive of Coulee. If solid neutral grounding is continued on the solid-bus scheme, the symmetrical value of fault kilovolt-amperes for a single-phase-to-ground fault would be approximately 15 per cent higher, or 14,000,000 kva. No allowance has been included in these figures for increased values of fault current due to transient offset which may increase the above values by an estimated 20 to 30 per cent. These fault magnitudes are considerably out of line with the maximum rated values of circuit breakers available at this time. Circuit breakers to meet these large values of fault kilovolt-amperes may be available by the time required; however circuit breaker rebuilding may be required

a reactor or bus segregation scheme is not adopted.

It is proposed to reduce the single-phase-to-ground fault magnitude of the solid bus scheme to 10,000,000 kva by the use of transformer neutral reactors. This means a further method is required to reduce 3-phase faults to the capabilities of present circuit breakers, or the interrupting rating of the circuit breakers must be increased.

Consideration is now being given to reducing the Bonneville Power Administration system insulation level in various locations. One of the main savings to be made by this reduction is in the cost of the transformer insulation.

Transformers operating at a system location whose ratio of zero-sequence reactance to positive-sequence reactance or X_0/X_1 is more than three, require full insulation, and protection by full-voltage rated lightning arresters. System locations having a ratio of X_0/X_1 of less than three may have 80 per cent lightning arresters and system or transformer insulation in the 196-kv class for a 230-kv system. With very low X_0/X_1 and R_0/X_1 ratios such as exist at Grand Coulee whose present ratio of X_0/X_1 is approximately 0.5 and with an expected future ratio of 0.4 (without neutral reactors), it may be possible to further reduce the transformer insulation level with a very considerable cost saving on future Coulee transformers. These transformers would then be protected by correspondingly lower-rated lightning arresters.

If the solid-bus scheme is adopted, the present 10,000,000-kva circuit breakers now being installed may have to be changed to larger circuit breakers in the near future.

Consideration should be given to the possibility of reducing future transformer insulation with its resulting saving in cost and improvement in reactance. This will require a low X_0/X_1 ratio. With the use of neutral reactors as a method of limiting ground current to 10,000,000 kva, this ratio may be increased above the value required to permit reduced insulation level.

Use of the ring-bus reactor scheme with full neutral grounding will permit a substantial saving in circuit breaker costs, as smaller sizes are required will save the cost of neutral reactors, and permit a possible saving in future transformer cost by maintaining low X_0/X_1 ratios to permit a reduction of insulation level.

V. M. Marquis and H. P. St. Clair (American Gas and Electric Service Corporation, New York, N. Y.): The authors have presented a very clear picture of the problem with which the Bureau of Reclamation was faced in deciding upon the switching layout and bussing arrangement for the Grand Coulee power plant. The various considerations leading to the final decision for installing a ring bus without reactors have been nicely set forth and we believe that a correct analysis of these considerations has been made and that sound conclusions have been reached.

On the 138-kv American Gas and Electric Company system, we have always felt that our high-voltage switching stations should be solidly bussed, and this practice has been generally followed. The only deviation has been in those cases where circuit breakers of adequate interrupting capacity were not available at the time. For example, at our Philo Station it was necessary to split the high-voltage bus into two sections separated by a large 138-kv reactor in order to limit the circuit breaker duty to the maximum of 3,500,000 kva then available in circuit breakers. Interleaved line connections with a split bus arrangement have also been used on a 66-kv system for similar reasons. In both cases a relatively heavy synchronizing tie has been maintained so that stability has not been affected. These practices however, have been regarded as temporary, to be discontinued when the necessary higher capacity circuit breakers are available. Operating experience has confirmed the superior flexibility of the solid bus, and for the Philo Station, plans are definitely made for the replacement of existing circuit breakers and the removal of the bus tie reactors.

We note that it is proposed to install reactors in the neutral of the 230-kv step-up transformers in order to limit line-to-ground faults to a maximum equivalent of 10,000,000 kva. This is undoubtedly a sound procedure, since, as the authors have pointed out, line-to-ground faults will be far more frequent than 3-phase faults, particularly for locations close to the power plant. We were wondering, however, whether the equivalent limitation in line-to-ground faults could not have been obtained in a less expensive manner by incorporating in the transformer design a moderate amount of additional insulation to permit operating some of these transformers with the neutrals ungrounded, relying on immediately adjacent transformer banks to supply adequate system grounding. This in effect utilizes the impedance of some of the existing transformers to limit the ground current and is a method which we have used successfully in two of our major power plants at 132 kv. In these cases 46-kv insulation in the neutral was adequate to permit leaving some of the transformers ungrounded. Perhaps the authors did investigate this possibility and found it to be more costly than the reactor scheme.

It is also believed that the authors have reached a sound conclusion in depending upon 10,000,000-kva circuit breakers for the ultimate layout even though a maximum theoretical 3-phase fault on the station bus of 12,000,000 kva is possible. The analysis of probabilities, as given in Figures 7, 8, 9, and 10, showing the likelihood—or absence of likelihood—of getting more than 10,000,000 kva in an actual system fault, does not lead to too much concern over the 12,000,000 kva possibility, particularly since some additional margin of capacity would probably be available in the circuit breakers themselves. In this connection it might also be pointed out that the full offset current wave which apparently is necessary to realize 12,000,000 kva would not necessarily produce the maximum condition of severity as far as circuit breaker interrupting capacity is concerned. The reason for this is the fact that when the wave is fully offset it is impossible to obtain a high transient recovery voltage, or rate of recovery voltage rise, since under these conditions the current and voltage both pass through zero at about the same time. This, of course, leads to a question as to the validity of our entire American practice in rating circuit breakers on the total rms value of current interrupted, even to the extent of taking into account a completely offset wave. European practice, as we all know, does not credit the circuit breaker with interrupting anything more than the a-c component regardless of whether the current wave is offset or not. We understand that some consideration is being given in this country to the advisability of changing our own practice in this respect.

For a generating station of the magnitude of Grand Coulee with its network of 230-kv outgoing lines, there does not seem to be much question but that the 230-kv ring bus operated as a solid ring with a number of normally-closed sectionalizing circuit breakers is a sound solution. It also appears reasonable to consider transformer differential operation of sufficiently infrequent occurrence that a clearing of the entire bus section would be justified. This would appear to be a satisfactory starting point at least and could undoubtedly be modified if future experience warranted it.

The apparently successful development of 10,000,000-kva circuit breakers is, of course the thing that has made it possible at Grand Coulee to operate a solid 230-kv ring bus, and corresponding developments at other voltages will also make possible the use of solid high voltage busses generally. This is gratifying to those of us who have followed these problems through the years and who have participated in some degree in development of higher capacity circuit breakers through field testing programs.

W. M. Leeds (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The importance of circuit breaker interrupting capacity in the determination of a suitable bussing arrangement for Grand Coulee power plant is made very clear both in this paper and in the paper by Hoard and Helwith. The operating flexibility inherent in a sectionalized ring bus system with minimum reactance between sections can be realized only if circuit breakers are made available of approximately three times the interrupting capacity of existing equipment. Considerable credit is due to the Bureau of Reclamation engineers for their confidence that such circuit breakers can be built, and particularly for their co-operation in extensive short circuit testing to verify the interrupting ability of sample circuit breakers submitted by various switchgear manufacturers.

In considering the 10,000,000-kva 230-kv 3-cycle oil circuit breakers now on order for Grand Coulee, it should be pointed out that these are special circuit breakers which deviate in several respects from established standards. In the first place, a continuous current-carrying capacity of 1,000 amperes has been specified to take care of particular emergency conditions, this being intermediate between the 800 ampere standard rating for 230-kv circuit breakers and the next step of 1,200 amperes available in circuit breakers at lower voltages. In the second place, the interrupting rating of 10,000,000 kva has been specified on a 20-cycle reclosing duty cycle. Since a derating factor is applied to standard circuit breakers used on this severe duty, it might be inferred that a higher interrupting ability is available on a standardcloseopen—15 second—closeopen duty cycle. In this case, however, the exceptionally high momentary currents for

this class of equipment that would be involved, together with a reasonable conservatism about extrapolating too far beyond the limits of past experience have made it desirable to avoid giving any kind of rating above 10,000,000 kva.

It is stated in this paper that the maximum line-to-ground fault current with the neutrals of the transformers solidly grounded would be 30 per cent above the 3-phase value, whereas Hoard and Helwith mention an increase of only 15 per cent. Would not the large figure apply only to the contribution from the Grand Coulee generators to a solid bus fault, the factor for the combined short circuit power including the contribution from the transmission system being perhaps an intermediate value of about 20 per cent?

Although it has been decided to operate the pump motors and associated generators separate from the rest of the system, if all 18 generators and 10 synchronous pump motors were to be connected to the system at one time, what would the estimated maximum 3-phase fault be then?

E. L. Kanouse (Department of Water and Power, Los Angeles, Cal.): This paper by Holmdahl and Killgore will be of great interest to all utility engineers. The locale of their problem is in itself of considerable interest, the largest hydroelectric power plant in the world, and the paper provides rather complete insight into the engineering analysis employed, with the results and conclusions following with complete logic.

Certainly the solid connection described as the solution to the bussing problem meets the requirements laid down by the authors. It is distinctly encouraging to know that the extremely high interrupting capacities required of the circuit breakers can in all probability be met by modern design.

However, there are many utilities for which the solid bussing arrangement to be employed at Grand Coulee would fail to meet a requirement not mentioned. This requirement would be that the short-circuit duties on lower voltage, subtransmission, and distribution systems not exceed certain nominal values.

In system planning studies recently conducted by the Los Angeles Department of Water and Power, it was found that power concentrations, within the city limits representing the combined contributions from both distant hydroelectric and nearby steam electric plants, would soon result in short-circuit duties in excess of 5,000,000 kva on the 138-kv backbone of the system. And while it was recognized that circuit breakers could probably be designed for this interrupting capacity, it was apparent that the existence of such high duties at the 138-kv level in the system would produce excessive duties on switches at voltages below this level in the distribution system. Extensive replacement of switches at 34.5 kv and below would be the inevitable result.

Accordingly, the city found it desirable to utilize a method of connections employing 138-kv air core reactors by means of which 138-kv circuit breaker interrupting duties may be limited to approximately 3,500,000 kva for an indefinitely expanding system. This will extend the useful life of hundreds of 34.5-kv switches in the distribution system.

Each of the city's six large receiving stations has been designed and operated to date as a double bus, double circuit breaker station. Current limiting reactors have long been contemplated in the busses, for separating the power source and load side of the station from the so-called belt line side. The belt lines, or interconnecting lines between stations, are designed as standby lines for carrying the load of the station in case the normal power supply is either interrupted or inadequate for any reason. Ten per cent reactors, on 100,000-kva base, have been purchased for the various stations, although studies showed that as the power system expands and additional receiving stations and generators are added, these reactors would fail to limit the short-circuit duty to the desired 3,500,000-kva level on the belt line side.

Figure 1. Double-bus single circuit-breaker belt line operation

The difficulty obviously arises because the use of double circuit breakers results in paralleling the two 10 per cent reactors in the busses, thereby halving their transfer impedance at each station. It was found that by utilizing double-bus single circuit breaker operation on the belt line side of all receiving stations, remarkable reductions in the short circuit duty of the belt line switches result. Furthermore, the studies showed that the power system can be expanded, by the addition of receiving stations either tapped or looped into the belt lines, to care for future load demands of at least 2,200,000 kw, and probably considerably more, without exceeding the interrupting capacity of many existing 138-kv circuit breakers.

The fact that this single circuit breaker method of operation reduces by half the number of 138-kv switches needed in the belt line positions is also quite attractive. However, the chief aim in developing the general system plan using current limiting reactors and belt line ties has been to hold the short-circuit duties down on the lower voltage subtransmission and distribution systems, and thereby avoid future extensive replacement.

It would be of interest to know the possible ultimate switch duties at the various points of bulk power delivery on the Bonneville system, such as at the 230-kv Columbia bus.

N. G. Holmdahl and C. L. Killgore: The various discussions of the paper have accentuated various sections of the paper to a marked degree as well as being personally gratifying to the authors. These discussions add greatly to the technical aspects of the subject.

Each of the discussions are treated individually and answers are given to the questions contained therein.

Lantz is concerned with two aspects of the problem of providing circuit breakers for the ultimate Grand Coulee power plant, (1) that 10,000,000-kva interrupting capacity circuit breakers will be too small with maximum generation both for a 3-phase fault and even more so for a single-line-to-ground fault without transformer neutral reactors and (2) that if too large a neutral reactor is used, the X_0/X_1 ratio will exceed three and thereby lose the benefit of reduced transformer insulation costs. He proposes that 230-kv bus reactors be installed to correct these conditions.

As stated in the paper, cognizance is taken of the fact that without using 230-kv bus reactors and for the worst possible conditions of fault, that is, maximum generation connected, full offset of the current wave and the fault occurring on a line immediately adjacent to the switchyard, that 3-phase faults may exceed the circuit breaker rating.

However experience has indicated the probability of the occurrence of such a combination of conditions simultaneously is exceedingly remote and that economically the additional capital investment for 230-kv bus reactors is not justified.

Plans are being made to install reactors in the transformer neutrals of such a value that the single-line-to-ground fault kilovolt-amperes will be equal to or less than the 3-phase fault megavolt-amperes. Such reactors will not increase the ratio of X_0/X_1, over three and will allow reduced transformer insulation with its reduced cost. Transformers now being purchased for the right power plant will have 196-kv insulation level.

From the foregoing, it is believed that Lantz' suggestions for reduced transformer costs will be realized without the additional cost of 230-kv reactors.

Smith suggests that a change be made in the bussing at the 230-kv switchyards such that no pair of lines to any intermediate substation would be terminated on the same bus section at Coulee. This point was considered in the preliminary discussions between the Bonneville Power Administration and Reclamation engineers but it was finally agreed to leave both lines, that is Coulee-Midway number 1 and Coulee-Midway number 2, connected to the same bus section for the following reasons:

1. All existing lines terminated in pairs at one bus section and rerouting would be costly and would add to the complexity of the switching stations.

2. With the future development of Columbia River, the 230-kv network would undoubtedly

become more solidly bussed with more high capacity ties, thereby minimizing the effect of the loss of two lines to any substation.

Crary's commendation of our paper is appreciated. In his discussion he points out that the recent circuit breaker developments leading to the development of the Coulee ring bus have come at an opportune time when many other American and European systems are planning to go to higher transmission voltages. It is by this mutual exchange of ideas and experience that the industry is able to meet the needs of the greatly expanding requirements of our civilization.

Dovjikov brings out a point which most of us are prone to overlook, that is that even though the designs and plans are based on the best knowledge available and the best interpretation of past operating experience, still the ultimate success of the Coulee ring bus will be determined by its actual performance in operation. The physical layout is arranged so that 230-kv bus reactors may be installed in the future if operating experience proves this to be desirable.

The authors appreciate Marquis and St. Clair's comments that in their opinion a correct analysis was made and sound conclusions reached, and for their discussion of the American Gas and Electric Company's experience with solidly bussed switchyards. From their point of view, a solid bus should be installed at all stations were it not for circuit breaker limitations which existed in the past. Their experience points to the desirability of omitting all bus reactors in order to simplify the operating procedures and remove any bottlenecks which reactors introduce. Such a statement reassures the engineers involved in the design of the Coulee bus, that their conclusions have basis in past experiences on other electric power systems.

The discussors suggest that operation of a portion of the transformers with neutrals ungrounded be considered rather than installing neutral reactors to reduce single-line-to-ground faults to the 3-phase value. Consideration was given to such a scheme but it was finally rejected as the costs in both cases were very nearly equal and it was felt that all units connected identically, that is with neutral reactors, was more desirable than having part of the units grounded and part ungrounded.

Leeds has amplified the special characteristics of the 10,000,000-kva circuit breakers now being manufactured for Coulee and in addition (a) questioned the value of 30 per cent for the increase of single-line-to-ground faults over 3-phase faults and (b) requested the value of 3-phase fault kilowatt-amperes if all 18 generators and 10 pumps were connected simultaneously.

In answer to the first point, Leeds is correct in his assumption that considering both line and generator contribution to a fault, that single-line-to-ground faults exceed 3-phase faults by only 15 per cent.

Present calculations of maximum fault megavolt-amperes are based on the contribution from 17 generators (one generator on 115-kv system) and nine transmission lines (assuming fault on tenth line just outside Coulee bus). The maximum calculated 3-phase fault on this system is 10,500,000 kva while with ten pumps in addition the fault is increased by about 700,000 kva.

Kanouse's discussion comments on the satisfactory use of 138-kv reactors in the Los Angeles Bureau of Power and Light system and requests information as to the effect solid bussing at Coulee will have upon circuit breaker duties at adjacent substations such as Columbia.

Considerable analysis of this problem has been done by the Bonneville Power Administration engineers on their network analyzer and results have indicated that at some points, circuit breaker duties will exceed the ratings of presently installed circuit breakers. In the conversion from the interleaved scheme to the ring bus, it was necessary to take an intermediate step before delivery of the 10,000,000-kva circuit breakers could be made. This step consisted of rebuilding six of the 8-cycle 2,500,000-kva circuit breakers for a 7,500,000-kva interrupting capacity for temporary use in line positions. These six circuit breakers will later be used by the Bonneville Power Administration after the ring bus is in operation for installation at such stations as Columbia and Midway where circuit breaker duties will be increased. It is believed that the balance of the Bonneville Power Administration stations will not be affected enough to make present circuit breakers obsolete.

The authors welcomed the several interesting discussions on the paper together with their comments and suggestions. At present, the left switchyard has almost been changed over to solid bus operation using 7,500,000-kva circuit breakers in the line positions. The changeover in itself has presented many interesting operating problems in maintaining full output of the left power plant at about 1,100,000 kw while making numerous circuit breaker moves in the left switchyard. However, as stated before, the left switchyard conversion is almost complete and operation with a solid bus will begin in December of 1948, with full ring-bus operation scheduled for the spring of 1949.

A New Outdoor Air Switch and a New Concept of Contact Performance

S. C. KILLIAN
MEMBER AIEE

The first electric switch used was doubtlessly a model of simplicity. It was likely made of two metallic wires or strips twisted together and when an open circuit was desired the two pieces were simply pulled apart. Something similar to the common knife switch was the next step and then as the industry grew, interrupting devices plus a host of special switches designed to do a particular job made their appearance. When electric equipment began to be used outdoors, another type of switch was born, the outdoor air switch. Due to adverse outdoor operating conditions such as corrosion and ice, it was quickly realized that some auxiliary blade motion was necessary if extreme operating forces were to be avoided. In the past 35 years, this auxiliary motion has led to a veritable maze of designs. The closest approach to perfection is in the gang-operated vertical break switch built on three insulators. Almost endless variety is obtainable in this one class alone. It is with this type that this paper deals.

In order to secure some auxiliary ice breaking motion and then raise the blade, many ingenious mechanisms have been used, most of which employ from 10 to 15 small moving parts. This complicity of bearings, cams, levers, links, gears, cranks, and knuckles inherently makes for trouble. The new switch, type *MK-40*, is the result of a search for simplicity and a desire to get back as close as possible to fundamentals with a minimum number of parts while retaining all the advantages of 30 odd years experience in switch design.

Paper 48-248, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted April 21, 1948; made available for printing July 29, 1948.

S. C. Killian is chief engineer with the Delta-Star Electric Company, Chicago, Ill.

The author wishes to acknowledge the assistance of N. Bond who conducted all tests and made valuable suggestions in test procedure.

Mechanical Design

Only three moving parts beside the blade are employed. These are shown in Figure 1A. Part *a*, bolted directly to the rotating insulator cap carries a double set of ball bearings at a 45 degree angle and drives the 45 degree knuckle pin, part *b*. This in turn rotates the blade through carriage *c* using another double set of ball bearings. The blade is bolted solidly in part *b* and completes the moving members. The blade makes point contact at both its ends with shoes *d*. No braids or flexible shunts are required. With the switch closed, the first 15-degree rotation of the insulator rotates the blade about its own axis, relieving contact pressure and exerting a large ice and corrosion breaking force. The next 23-degree insulator rotation produces a blade rise of only 10 degrees, providing in this ratio a sizable mechanical advantage exactly where it is needed. Figure 1B shows the mechanism parts with the blade partly open. For the final part of the blade lift where no mechanical advantage is required, the blade rise in degrees exceeds the insulator rotation in degrees. Figure 1C shows the switch fully open. The identical sequence in reverse occurs as the switch closes. The simplicity of design and motion is readily apparent. It is interesting to note that the blade is locked in both open and closed positions by having the knuckle pin move over dead center in both positions. The blade is under positive control during the complete cycle, requiring no stops or auxiliary devices to impart the turning and lifting motions. Figure 1D gives a close-up of the contact and bearing construction at the hinge.

Small members are studiously avoided in the entire design. After years of service, corrosion can cause small members to weaken or fail. Spring members especially are to be kept as large and heavy as possible. A three-leafed spring of 3/16 inch beryllium copper (9/16 inch total thickness) is used on each side of each contact on this switch. A large spring deflection, 3/16 inch total, is used so that wear on the contacts and blade over a period of years will not materially effect the contact pressure. Bearings are made large which reduces ball bearing pressures. Moving parts are exceptionally husky.

Contrary to some contact design thinking, the spring member and the hard drawn copper current carrying member are independent. No alloy can be compared to copper for electrical conductivity. When independent of the electric circuit, the best spring available can be used. When the contact and spring members are combined, some of the ideal characteristics of each must necessarily be sacrificed.

For voltages above 69 kv the weight of the blade is effectively counterbalanced by the use of enclosed torsion springs mounted directly at the hinge pins of each unit. The switch is constructed in 400, 600, and 1,200-ampere capacity from 7.5 kv to 230 kv. Higher capacities are built with square tubing blades in a somewhat similar design. These have been in service since 1941. A 4,000-ampere 23-kv unit is shown in Figure 2. Counterbalance spring housings are shown at A.

Electrical Design

Because an air switch must operate in all kinds of weather and in contaminated atmospheres, trouble experienced has been more of a mechanical nature than electrical. This has led to emphasis being placed on mechanical features and design rather than electrical. Though the elec-

Figure 1. The new switch, 600 ampere capacity, showing mechanism and contact details

trical design is less complicated than the mechanical, it is of primary importance and will become more and more important as the enlarged capacities of many systems will put ever increasing short-circuit loadings on such equipment. In addition to carrying its full load under a given temperature rise, and employing contacts which will give satisfactory service under bad atmospheric conditions, the design must be such that short-circuit currents will be handled without distress. A high pressure, small area contact such as used on all switches of this type is basically a spot welder. The only reason contacts do not weld together under high fault currents is the ability of the contact to carry the generated heat away quickly, and also provide a volume in which to store this heat. By using hard drawn copper parts for all current interchange members, advantage is taken not only of 100 per cent electrical conductivity but of a very high thermal conductivity. The law of Wiedemann and Franz states that for metals at a given temperature

$$\frac{\text{Thermal conductivity}}{\text{Electrical conductivity} \times \text{absolute temperature}} = \text{Constant} \qquad (1)$$

In this simplified formula, if the thermal conductivity is given in joules per centimeter per second per degree centigrade, the electrical conductivity as the reciprocal of the resistivity in ohm-cm $\times 10^6$ and the temperature as 0 degree centigrade, the constant according to Cork[1] is approximately 2.3 (10^{-6}) in joule ohms per second per degree centigrade squared. All metals, by taking the ratio of their two conductivities, produce this same value, approximately 2.3. The writer has calculated this ratio for alloys and finds that the law holds just as rigidly as for pure metals.

It follows therefore that a high electrical conductivity and high thermal conductivity go hand in hand. Copper has a thermal conductivity of 0.92 gram-calories per square centimeter per degree centigrade per centimeter at 20 degrees centigrade, as compared to approximately 0.30 for various copper alloys and bronzes. According to Moore[2] the thermal capacity for unit volume for materials which would usually be used in contacts varies over a range of 40 to 56 watt seconds per cubic inch per degree centigrade. The value of 56 is given for copper. The volume of the contact is of even greater importance for it is this mass which must act as a heat sink when a short circuit occurs. The copper contacts on this switch are 1/4 inch thick and are very ample for rated short-circuit duty. Double shoes are used at both ends of the 1,200 ampere design as shown in Figure 3 to afford four points per contact. Copper blade walls vary with both current and voltage rating and are in keeping with contact sizes. As the blade itself makes contact with the shoes, the number of current interchange surfaces as well as the number of moving parts are held to a minimum. Temperature rises at rated currents are well below the allowable 30-degree centigrade value.

Contact History

This switch carried a high pressure small area type contact at both ends of the blade. It is extremely interesting to search back into the history of this contact which is now almost universally used on air switches. Some of the historical highlights follow. In 1906, Browning[3] realized the importance of pressure as related to contact resistance but probably due to the large areas he used, 1.54 square inches, found a point at 30 to 35 pounds per square inch beyond which an increase of pressure produced no additional drop in resistivity. In 1912, Binder[4] studied contact shapes and conducted comprehensive tests in which he attempted to show that contact drop was a function of pressure alone. In 1913, apparently quite independently, Harris[5] published four laws of contacts, the fourth of which read as follows: "The resistance between contacts depends not upon their area but only on the total pressure with which they are forced together."

Figure 2. 4,000-ampere switch

Figure 3. The new switch, 1,200 ampere capacity

A considerable quantity of material on this subject appears in the literature following the above dates, probably the most notable of which is that by Schaelchlin[6] and Contius.[7] In the generalized formula

$$r = \frac{k}{p^n} \qquad (2)$$

where

r = contact resistance
k = constant depending upon contact shape
p = pressure in pounds
n = constant depending upon contact surface

Contius (from Windred[8]) evaluates comparative contacts. The constant n varies from 0.5 for points and crossed cylinders to 2 for small plane surfaces of 2 and 3 square-centimeter area while k shows a minimum of 0.00015 for crossed cylinders and 0.00020 for points as compared to a maximum of 0.4 for ground planes 3 square centimeter area.

Of more recent date is a book by Windred[8] and of very recent date an

exceptionally thorough book by Holm[9] both of which deal with contact theory. For a general bibliography on the entire subject the reader is referred to the American Society for Testing Materials Contact Bibliography.[10]

Contact Design

Though a large amount of literature is available on the subject of high pressure contacts, no one has apparently tried to explain their superiority to large area contacts by means of diagrams such as shown here. Figure 4A shows a contact shoe of the new switch with apparent contact area shown shaded. Since the shoe is formed on a radius and the tubular blade is formed with rounded edges, the contact can be compared to two cylinders crosswise. Figure 4B illustrates a large-area medium-pressure contact. Authorities now definitely agree that it is impossible to grind two contact surfaces flat so that they touch at all points. The large-area contact of apparent area *lw*, will touch at only three points as shown by shading, Figure 4B. The area of these points will be determined by the pressure on the contact as well as by the hardness of the contact material. If the material is soft, these high spots will flatten and possibly new contact points will form. Of the shaded areas only those spots shown in black will conduct current. These spots are called A-spots by Holm.[9] The remainder of the shaded area, due to always present films such as oxides and sulphides, does not make a good conductor. On the other hand in Figure 4A, the apparent contact area is approximately equal to the shaded area or actual surface contact area. The total area of the A-spots is larger than those in Figure 4B because the higher pressure used in Figure 4A allows for more shaded area, more intimate contact, more film breakdown due to pressure means and consequently larger A-spots. This discussion refers to nominally clean contacts. Heavily filmed contacts are discussed in the following section.

It so happens that for the ordinary large-area contacts the blade must be withdrawn as in a knife switch. High contact pressures cannot be used, as the operating effort becomes excessively high. With the point or line contact, however, pressure can usually be released before moving the switch blade away from the contact and this results in easy operation. If sufficiently high pressures could be used on large-area contacts, there is no reason why they should not function equally as well as contacts of smaller area. This very likely explains the perfect record of hinge contacts on hook stick switches. Here, in most designs, pressures of the order of 400 or 500 pounds, provide a very satisfactory contact, even though "apparent" contact areas are large.

Contacts at both the break end and hinge end are made up of the hard drawn copper blade operating against rolled silver inlays on hard drawn copper shoes. This combination of metals was picked after a long program of contact abrasion testing on many materials because it provided a contact with abrasion-free characteristics. Contact pressure is approximately 200 pounds. An approach to a point contact is used rather than a line contact because of ease of adjustment. One can see readily that even though the shoes or blade be slightly misaligned the contact between them (2 crosswise cylinders) will not be affected. If a line were used on either of these members against a surface, a slight misalignment would make it very difficult to get the line to lie flat on its engaging surface. A point contact would therefore result.

The Effect of Films on Contact Performance

Contact films must be given more consideration on outdoor air switches than on any other type of equipment. All air switch contact literature and technology to date have dealt with only clean contacts. However, usually by the time the switches are installed they already have accumulated some film, and as they are in use for practically their entire life in a filmed condition, this feature requires definite consideration. As these contacts are entirely exposed to corrosive atmospheres, film growth occurs very readily and these films play an important part in reducing the contact's efficiency. The resistance of the various films which ordinarily form on air switch contacts in use today are extremely high. Silver oxide and silver sulphide, though of very high resistivity at room temperature, are decomposed comparatively readily under heat. The oxides and sulphides of copper on the other hand do not break down readily under heat.

Figure 4. Comparison of contact area of high-pressure small-area contact and medium-pressure large-area contact

Other phenomena help puncture these films, however, and it is likely due to these that very badly corroded contacts function at all when closed after standing open for long periods of time. Possibly the most important phenomenon in this respect is "coherer action" (see Holm[9]). This action is thought to take place as follows: If the film is of high resistance, free ions will migrate through the film, after which fluid metal will form exceedingly fine bridges across the film. (Estimated diameter = 400 Angstroms[9]; 1 Angstrom = 10^{-8} centimeters). These bridges form at a critical voltage, called the "coherer voltage" which is related to the melting point of the particular contact metal as well as to the thickness of the film. In testing for this critical voltage, large initial contact resistances are read. Voltage is gradually increased until some voltage is reached where the resistance suddenly falls to a very small fraction of its original value. This coherer voltage is usually of the order of a few volts or less on thin films, though Holm did require as much as 100 volts to break down a nickel oxide film 1,250 Angstroms thick. This phenomenon is not dependent on any combination of metals or circumstances, but occurs on all metals and through all types of film. Coherer action through varnish films has been shown and Pearson[11] has proved that this action occurs on contacts actually separated by small distances, in which case the film is air.

As far as can be found by a careful search of the literature, few tests have been made on filmed contacts on an actual switch. Also, the literature, including Holm's very complete work, deals with film breakdown largely from a voltage standpoint. For pure physics this makes an ideal method. The usual method, however, of checking contact efficiency on an air switch is to take a millivolt drop across the contact with some constant voltage on the whole set-up. This drop then becomes a function of current and with this in mind it was decided to investigate films from a current standpoint.

This is closely related to voltage breakdown for when current is increased over a contact, a larger voltage will appear over the contact for an instant. While not as exact as the voltage method, it is more practical on switches of this kind. Air switch contacts usually have a plentiful source of voltage available to break down contact film, for in actual operation of a system, thousands of volts may appear across the contact if its resistance is very large. More research on voltage breakdown remains to be done, for film studies so far published have not dealt with films nearly as thick as those which accumulate on outdoor switches.

This method of testing also brings up the question of whether tests should be made on corroded contacts at some small current or at currents close to the rating of the device. Almost any current might be used in order to get a drop across the contact, varying from a fraction of an ampere to hundreds or thousands of amperes. If films are broken down by currents close to the contact's rating, testing with small currents will produce erroneous conclusions.

For the purpose of checking films on contacts composed of different materials, a contact such as that on the break end of the new switch was chosen. Four contact combinations were tested as follows: rolled copper shoes and bronze blade (a tin, lead, zinc, bronze of 20 per cent electrical conductivity); rolled copper shoes with silver inlays and a silver plated copper blade; rolled copper shoes with silver inlays and copper blade; rolled copper shoes and copper blade. The copper blade in all cases was hard drawn copper tubing. It was felt that these four combinations would provide information on most contacts in use today. Pressures of approximately 200 pounds per point were used. Drops were taken from point x to point y, Figure 1A, which included the entire length of the shoes and part of the adapter casting. The resistance from x to y with clean contacts was approximately 35 microhms for all four contact combinations. All contacts were 600-ampere capacity. Direct current was used in making measurements. After measurements were taken, a-c heat runs were made. These showed that the passage of alternating current through the contact did not change the contact's resistance if the alternating current was of the same order of magnitude as the direct current.

Any film deposited on a contact is relative since there is no standard method of procuring a dirty contact or an oxidized sulphided or corroded contact. Films

Figure 5. Resistance characteristics of sulphided contacts

are deposited on outdoor switch contacts by corrosive atmospheres. The action of these atmospheres can be simulated by putting the contacts in a chamber which is then filled with active gases. This procedure is slow however for repetitive testing, and accordingly was not used. The first set of tests was made on contacts sulphided with a solution containing one part by weight of potassium sulphide to nine parts water. This solution was applied to the blade and contact of the open switch with a glass rod, so as to completely wet the contact surfaces. The solution was left to dry overnight. A dense, strongly adhesive, black sulfide film resulted on copper, bronze, and silver surfaces. No method was available for measuring the film thickness but it was of such order that any maintenance man would recommend cleaning these contacts if he had them on his system. Great care was taken to apply the corroding agent in an identical manner to each contact and to each set of tests. That this was accomplished was shown by the closeness with which most curves followed preceding curves on the same contact. The switch was closed (only one closure made) and readings were taken.

Test results were most interesting and are shown in Figure 5. At currents of about 1/2 ampere, resistivities of several hundred thousand microhms were found on both copper-copper and copper-bronze. If smaller currents were used, it is very likely that even higher resistances would have been found. As the current was increased, the resistance fell continuously until it was only 300 to 500 microhms at 400 amperes. The sulphides and oxides of copper are extremely adherent and it is not likely that any switch contact can wipe them away. This has been forceably demonstrated on connectors with toothed surfaces, clamped on oxidized copper wire. Even though thousands of pounds of pressure were available by means of clamping bolts, the oxide film was not cleaned away. This explains the need of such a phenomenon as coherer action in order to make the copper-copper and copper-bronze contacts suitable conductors.

A most revealing phenomenon occurred on these two contacts. It was found that after a current of a few amperes was exceeded, the voltage drop across the contact was almost constant, up to several hundred amperes. This, of course, meant that as the current went up, the resistance came down proportionately. On the basis of Holm's theory that small filaments of molten metal were formed through the film, we could deduce that each rise in current caused these filaments to grow in exact proportion to the current.

A digression seems appropriate here in analyzing short-circuit currents on heavily filmed contacts. If the connecting filament does grow as suggested before, it will attempt to grow very rapidly when the current suddenly increases from a few hundred amperes to many thousand amperes under short circuit, and the accompanying evolution of heat and gases will probably blow the contact apart momentarily if the parts are not held together with sufficient pressure. This will cause arcing, sputtering, and burning and may explain the occasional burning on corroded medium pressure, large area contacts. The scope of testing in this project was limited to only load currents. Further testing on the behavior of various filmed contacts under short-circuit conditions is planned for the near future.

Unlike the copper-copper and copper-bronze contacts, the copper-silver normally showed a much lower resistance. Resistances of approximately 200 microhms appeared at small currents. This decreased gradually at increased currents until values of approximately 100 microhms were reached at 400 amperes. In two cases out of six tested, this combination showed a characteristic similar to the copper-copper characteristic, but was much lower in initial and final resistances. This cannot be explained readily, but some explanation was suggested in the contact condition. This will be discussed later.

The silver-silver contact performed very well, producing resistances of approximately 40 microhms at all currents. Three possible explanations for these

low readings offer themselves: (1) film disintegration due to heat from the passage of current; (2) Holm's filament formed through the sulphide in such large diameters, due to the ready breakdown of the film, that low resistance immediately appears; (3) the sulphides of silver are not as strongly adherent as the sulphides of copper and are wiped away when the switch closes. Probably (1) and (3) together make this combination a particularly efficient one. (2) is not likely. These remarks also apply to the copper-silver contact in a lesser degree.

Tests on oxidized contacts were next made. Results are shown in Figure 6. The oxidizing agent was applied in the same manner as the sulphiding medium. A commercial oxidizing agent was used which produced a heavy coating of cupric oxide and silver oxide. Results followed those of sulphided contacts quite closely, though values as high as 775,000 microhms and 575,000 microhms were recorded on copper-bronze at low currents. Copper-silver showed constant average values around 100 microhms in five of six tests. The sixth test showed a characteristic similar to copper-copper but much lower in initial and final resistance. Silver-silver repeated sulphided values at a constant of approximately 40 microhms. The same line of reasoning as applied to sulphided contact performance, holds for oxided contacts.

Tests on contacts coated with a solution composed of equal parts of the sulphiding and oxidizing solution were next performed. Results are shown in Figure 7. The characteristic pattern again appeared, copper-bronze producing a high value of 839,000 microhms. Of six copper-silver tests performed with this film, three showed constant readings of approximately 100 microhms while the other three showed a falling characteristic from approximately 1,000 microhms to 250 microhms. An average curve is shown. Some possible explanation for this is offered in the next paragraph. The silver-silver contacts showed a constant resistance of about 40 microhms.

On all tests made, contact performance was checked for reversible characteristics. This was done by reducing the current through the contact after maximum current was reached. Without exception it was found that the phenomenon is not reversible and that the contact resistance remained approximately constant. This is illustrated in Figure 5 by the return curve indicated by fine lines and arrows. Contact resistance could be raised very materially by striking the channel base of the switch repeatedly with a mallet. This apparently broke or damaged the filament through the film.

Another contact phenomena was studied when several sets of contacts were highly burnished before being coated. This was done by operating the switch many times until a very high polish was obtained on the contact surface. Just as plating on a highly polished surface produces a highly polished plate, the half oxide, half sulphide solution produced a polished film on this surface. Of three silver-copper contacts tested, all showed the characteristic decreasing resistance pattern. Highest readings obtained at 1/2 ampere were 90,000 microhms which fell to less than 300 microhms at 350 amperes. Even the silver-silver combination showed relatively increased resistance under this polished condition, the one test performed producing 960 microhms at 1/2 ampere which fell to 160 at 350 amperes.

The literature produces verification of this. Schaelchlin[6] found that on contacts exposed to the air for one week at 30 degrees centigrade, a contact roughened with emery cloth produced lower resistances than what a carefully ground contact did.

In formula 2 Contius[7] includes a value n for surface condition. He further states that "particularly smooth surfaces are characterized by high resistances."

In all tests with the exception of the four previously mentioned, contact surfaces were prepared by cleaning with medium fine steel wool before applying the film. In these polished cases not only was the action of the polished contact being effected, but due to the smooth surface the closure of the switch failed to clean away any considerable film. This particular test was not tried on the copper-copper or copper-bronze combinations as they already showed very high initial resistance values. On the silver-copper contacts tested with no burnishing it must be supposed that the silver film helped in some measure to destroy the copper film mechanically as a general rule. When higher initial resistance values appeared on this combination it is likely that the film was not broken down mechanically. Burnished contacts such as these are not a possibility in the field, of course, because many operations will not be put on the switch in an hour or so and corrosion formed will prevent such a polish appearing when many operations are put on the contacts over a period of months.

One additional study was made on non-polished contacts filmed with the sulphide and oxide solution. The contact shoes were held apart until the blade was in place and then released, so as to avoid any wiping action. On three tests made with copper-silver contacts, high values of 160,000, 29,000 and 288,000 microhms were found at 1/2 ampere. These fell to the usual low values at 350 amperes. On one silver-silver contact tested a constant resistance of about 50 microhms appeared.

This proves further that the silver film must help break down the copper film mechanically when the switch is closed in the usual manner.

All resistance curves seemed to become almost horizontal at the limits of currents tested, 350 to 400 amperes. In order to check this, tests were continued on several runs to currents as high as 900 amperes. The general shape of the curve followed predicted values very closely. At 900

Figure 6. Resistance characteristics of oxidized contacts

Figure 7. Resistance characteristics of sulphided and oxidized contacts

amperes, resistance values of 200 to 250 microhms were found where values of 400 microhms existed at 350 amperes, showing that in the higher current ranges, resistance decreases very slowly with an increase in current.

A total of 66 tests were made on these various filmed contacts and it is thought that they should be of sufficient quantity to fully support the conclusions reached here.

Conclusion

The new switch combines the following necessary engineering features: minimum number of moving parts, substantial construction, minimum number of current interchange surfaces, proper contact design and all around simplicity. Though silver-silver contacts proved best on film tests, their abrading characteristics under high pressure prevent their use. Copper-silver makes an ideal antiabrasive combination and provides a superior electric contact when compared to copper or the copper alloys. Additional work remains to be done on testing filmed contacts and it is likely that this particular contact condition will receive more and more attention.

Discussion

J. B. Owens (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The paper describing the new outdoor air switch reveals that a simple design with a minimum number of moving parts has been achieved. However, some features which experience has shown to be desirable in outdoor switches have not been included.

The jaws on the hinge end of this switch form a pocket where snow and ice will collect, making the switch more difficult to operate under adverse weather conditions. Unfortunately it is not possible to enclose the jaws on both ends of an air switch; but it is desirable to cover the contacts on the hinge end. The addition of a cover over the hinge jaws would keep off ice, and in addition would keep the contacts comparatively clean thus reducing the maintenance required.

The blade actuating mechanism of the new switch appears simple and sturdy; however, a possibility for improvement exists in the design of the bearings above the rotating insulation column. The author states that large diameter ball bearings are used to reduce the ball pressures. These may be called upon to stand in the weather for long periods without operating or lubrication. If ice or corrosion fouls such large bearings they will be much more difficult to break free and operate than smaller diameter bearings because there is more surface to become fouled, and bearing friction operates on a greater radius so that a poorer mechanical advantage is available to overcome it. Small diameter bearings with materials which are suitable for the increased bearing pressures are desirable in outdoor switches.

The results of load current tests described in the paper prove the ability of the contacts to carry rated current. However, the paper states that short-circuit current tests were not made. Tests in our laboratories at currents up to 250,000 amperes for five seconds have positively shown that a line contact will carry more current without damage than a comparable point contact. The author points out that it is the metal immediately adjacent to the contact which determines the rate at which heat is conducted away and thereby determines the short-circuit current which can be carried without damages. A line contact inherently has a much greater amount of metal immediately adjacent to the contact and thus greater short circuit capacity.

The results of the test on electric contacts with oxide and sulphide films are of considerable interest. The author is to be congratulated on the application of classical contact theory to the explanation of air switch contact performance.

J. A. Adams (Philadelphia Electric Company, Philadelphia, Pa.): During the last few years there have been a number of new disconnecting switch developments, one of which was described previously in an AIEE paper.[1] The present paper is another contribution to this line of development. It shows that considerable thought has been given to both mechanical and electrical problems which affect the operation of these switches in actual service.

From an operating company viewpoint a switch should:

1. Be mechanically strong.
2. Be durable.
3. Be easy to install.
4. Be easy to operate.
5. Require little maintenance.
6. Have good current carrying capacity.

It would be hard to say which of these points is the most important; certainly, all of them have to be taken into consideration in the development in order to produce a well balanced design which will continue to give reliable service.

It goes without saying that the switch must be strong enough mechanically to withstand the operating forces and that it must do this under adverse conditions, such as when coated with ice, as well as withstand the stresses created by heavy short circuit currents. Also, all parts of the switch should be sufficiently durable to stand up under years of severe operating conditions. Delicate parts and adjustments have no place in this type of equipment. The switch should be designed so that it can be installed with a minimum of adjustments and they should not be critical. The necessity for ease of operation is obvious. From an operating viewpoint, low maintenance is one of the more important factors. This requires a design with as few moving parts as possible, and with few if any members which can get out of adjustment during operation. Elimination of braids is a step in the right direction. Not only must the switch be able to carry its normal current rating without excessive heating and with low contact drop and be able to carry short circuit currents without pitting of contacts, but it should also have the ability to carry heavy overload currents for short times without difficulty.

The foregoing factors should be taken into account not only in the design of the main switch but should also be incorporated into the design of grounding blades. While these blades may not be used frequently, they are just as important as the main blades when they are required. Another point of importance, not covered, is the design of the operating mechanism, which should take into consideration the mechanical factors discussed.

In the paper it is shown that although the contact resistance for copper-to-bronze and copper-to-copper contacts with films is initially high for small currents, it drops to relatively low values with increasing current where it remains even when the current is again reduced. In this connection, I have the following questions: For sulphided or oxidized contacts is it necessary to raise the current to high values before the lowest value of contact resistance will be obtained or will the contact resistance drop with continued operation at low current? For example, referring to Figure 5 of the paper, if the current is initially of the order of 75 amperes and remains at this value for a relatively long time, will the copper-to-bronze contact resistance remain at approximately 1,090 microhms, or will it eventually drop to the value of about 320 microhms as indicated for the final resistance? Does the operating voltage affect these values?

Low voltage tests made by the Philadelphia Electric Company on some new 88-S

Figure 1. Close-up view showing contact end of switch with blade in fully-open position

Figure 2. Close-up view showing blade in partly-closed position

kv, 1,200-ampere switches which had become tarnished while they were stored outdoors showed high contact resistance and high temperature rise at rated current. The temperature rise of the clip end contacts which were silver-to-copper was from 2 to 16 degrees centigrade above the standard AIEE rise of 30 degrees centigrade, while that of the hinge-end contacts which were copper-to-bronze was 36 to 50 degrees centigrade above the standard value. When the contacts were cleaned the temperature rises dropped to normal values. These tests indicate that careful attention should be paid to contact design and that contacts not seriously affected by films are to be preferred.

While the author indicates that this switch is constructed up to 1,200 ampere capacity in voltages up to 230 kv, it seems desirable to point out that there is now a need for 2,000 ampere capacity at 69 kv to match available circuit breaker ratings.

The switch described appears to offer the mechanical and electrical features desired for this type of equipment. It will be interesting to compare the service record in a few years with the present views on this development.

1. A New Outdoor Air Switch and the Principles Involved in Its Design, H. W. Graybill, J. S. Ferguson. AIEE Transactions, volume 64, 1945, pages 583–6.

F. C. Brogan (The Ohio Public Service Company, Cleveland, Ohio): This paper appears to go a long way toward crystallization of some of the thinking regarding design of air switches. The frequency of operation of these switches varies considerably in the many locations where they are used; also the weather and contamination conditions vary considerably, the main effect of which is a very wide variation in the operating duty imposed upon the switches.

A reduction in the number of parts is certainly a step forward, as is the reduction in number or elimination of braids or flexible shunts. Undoubtedly improvements have been made in the fabrication and lubrication of flexible shunts but troubles still crop up, particularly in locations where contamination is a serious problem, and the elimination of flexible braid is commendable.

The separation of spring member and current carrying member also appears to be an improvement, particularly since most metals or alloys do not rate high in both respects.

Both the electrical and mechanical properties of switches are important and it is agreed that increased short-circuit loadings on most systems place a greater duty on the switches, evidence of this having shown up in many instances in recent years.

We have had in service for over 20 years, so-called high pressure contact air-break switches, and with very little maintenance (principally in replacement of braid shunts) the operating experience has been very good. One of the principal faults with these switches was the difficulty of operating them manually, which was partially overcome by using unusually long swing operating handles.

The matter of contact pressure apparently is open to considerable difference of opinion but it appears that too high pressure involves too much force in the opening and closing; also may bring about spot welding effect between contacts (either due to limited contact area or too high contact pressure) and may result in wear and erosion of contact areas, particularly so if subjected to high currents and annealing of contact metals occurs. We believe that contacts designed with larger radii of the members and with only moderately high pressures might eliminate some of these difficulties. It is believed that the limitation in contact pressures in order to avoid excessively high operating effort might be overcome by the gear box and crank operating mechanisms now generally used, especially on the high-voltage switches. Use of gear box and crank mechanisms might permit a design of greater contact area with softer metals or alloys and retention of moderately high contact pressures without too severe contact abrasion.

We note that rolled silver inlays for one-half of the contact was tested against bare copper for the other half of the contact; also against a silver plated blade contact. Tests for the silver-silver contacts apparently indicated this was a very good combination which leads us to wonder why the silver inlay to copper combination was finally selected. We would expect from the report that silver-to-silver contacts would be the best design, particularly if silver inlays were practical for both members of the contacts without excessive abrasion. Silver plating in a laboratory test may prove very effective but in actual field service it is believed that the silver inlays for both halves of the contact would stand up much better providing contact pressures used are not excessively high and providing the area of contact is not restricted too seriously.

The approach to this design problem seems to have been very thorough, particularly in the attempt to co-ordinate experience and theory, and to meet more severe duty requirements. The tests indicate that some worth-while improvements have been made. Further tests, and especially service experience in the field should indicate whether some of the conclusions are correct.

A. H. Powell (General Electric Company, Schenectady, N. Y.): The author is to be commended for the fine way he has presented a comprehensive review of considerable information concerning contacts. On the basis of the information and actual test data, he has arrived at another design of contact. While the paper, according to the introduction, was intended to deal with both a new outdoor air switch and the broad subject of contacts, it is noted that only a short section of the paper actually dealt with the new switch and most of the information presented concerned contacts.

In connection with the new switch, it is noted that there is direct connection between the rotating insulator and blade through a so-called knuckle pin, and it would appear that rotation of the blade would cause vertical movement, although very slight, as the switch approaches the fully closed position. Such movement would be generally objectionable due to the resulting forces which may bend the blade, especially if ice is present. A diagram showing the torque required to operate the switch in relation to the blade position would have clarified this point.

Most of the paper deals with contacts and the author has given a bibliography of pertinent information and test data to point out the fact that a silver-to-silver contact from an electrical point of view is the best

Figure 3

obtainable. However, it is further pointed put that under high pressure obtained with point contacts the soft silver surface is easily worn and the author concludes that a copper-to-silver contact would be superior. Figure 1 of the discussion shows the contact end of a new switch that was recently introduced to the industry, with the blade in the closed position before contact pressure is applied. Figure 2 of the discussion shows the contact after the blade has been rotated. Multiple flat copper fingers, each providing a short line of silver, backed by individual springs are used with approximately 50 pounds pressure on each contact line. The end of the blade is also silvered. With this construction the preferred silver-to-silver contact is obtained, the design prevents misalignment and distributes the pressure to prevent scoring.

Figure 3 of the discussion shows some interesting basic resistance information obtained in a laboratory with silver covered surface, point, and line contacts. Curve "B" shows that a pressure of approximately 50 pounds with a line contact 1 inch long results in practically the lowest resistance obtainable with a reasonable contact pressure.

Sulphiding of silver contacts is, of course, a problem and it was found nearly ten years ago that a silver button contact on a control switch had a resistance of 150 microhms when perfectly clean, but a resistance of 600,000 microhms when badly sulphided using currents in the order of 0.05 amperes. The resistance decreased as the current was increased up to a maximum of 100 amperes, when the resistance became 250 microhms. Higher currents would apparently have lowered it further.

This paper has confirmed other available information which shows that sulphiding of silver contacts in disconnecting switches operating at currents of several hundred amperes is probably not a serious problem. However, more information concerning dirty contact under short-circuit conditions would be very desirable.

S. C. Killian: The author wishes to thank those who commented on the paper and is pleased that it warranted such a complete discussion. Adams' six required points are of great importance and almost embody the basis on which the new switch was designed. The operating mechanism was not discussed because of space limitation. This is however an important factor and must be considered in any over-all switch design. The question regarding contact resistance versus time is a good one. Though no long-time tests were conducted to check this, it seems quite certain that holding a given current for a long length of time on a contact will not reduce its resistance. Operating voltage effects the resistance only when the voltage is very low and the film very thick. Then extremely high readings are obtained say at six volts. If the film is broken down by, say 20 volts, lower readings are immediately obtained. These are then further reduced by larger currents at six volts as shown in Figures 5, 6 and 7 of the paper. Conclusions reached in the paper are verified by the interesting heat runs conducted by Philadelphia Electric Company. Air switches, 2,000 ampere 69 kv, similar to Figure 2 of the paper are designed and have been in operation on the Buffalo-Niagara system for several years.

Owens' remarks on open contacts might seem important until one realizes that one contact must withstand adverse atmospheric and weather conditions. If the break contact is good enough to do this and it is agreed that it is a satisfactory contact, it is only sensible to design the hinge contact in a similar manner. A big majority of utilities and manufacturers now feel that open contacts which cannot trap snow and ice are to be preferred to covered contacts. Very large openings and clearances are used at both contacts of the new switch and it has passed all conceivable ice tests with no difficulty. Ice which collects around bearings is broken in tension and shear on well designed switches and is consequently of little importance. Short-circuit tests were made on the new switch but on clean contacts, just as all other tests in the country are run. To quote from the paper "Further testing on the behavior of various filmed contacts under short-circuit conditions is planned for the near future."

The remarks in Brogan's opening paragraphs are very well taken. The elimination of braids on air switches has been a definite step forward, as the almost universal adoption of the braidless switch by most utilities and manufacturers will attest. Contact pressures must be high enough to keep the contact parts in intimate contact under short circuit, or sputtering, arcing, and burning will occur. High operating effort can be avoided by securing mechanical advantages not only at the handle or operating gear box but in the live switch mechanism itself. The new switch contacts use silver inlays against copper because silver-to-silver galls at pressures which it is felt are required to successfully withstand short circuits.

Powell's point that the switch blade does have a very slight vertical motion is true. A travel diagram is shown here as Figure 4. The blade rise in the first 15 degrees of motion necessary to relieve contact pressure is less than one degree. This motion is so small as to be unimportant when compared to the large axial rotation of the blade in the powerful ice breaking movement. It is felt that the 50-pound contact pressure mentioned by this discussion is insufficient to provide a contact that will not burn and pit under bad atmospheric conditions and heavy short circuits, even though all silvered. Observations on line contacts are interesting, but definitely only on the academic side. It is virtually an impossibility to get a line to lie flat on a plane. On a nonprecision device such as an air switch where the blade is usually hinged several feet from the contact, misalignment is always present. This, even in very small degree, will allow the line to contact the plane at only one point, thus providing a poor point contact. The values shown in Powell's Figure 3 can have no significance for he is dealing with clean contacts and a difference of only a few microhms.

In his next sentence he mentions sulphided silver contacts, quoting values of hundreds and thousands of microhms. A few microhms difference is microscopic where filmed contacts are concerned and all contacts are filmed on switches for service, even before they are removed from the crate.

Problems in the Measurement of A-C Resistance and Reactance of Large Conductors

E. H. SALTER
MEMBER AIEE

IN connection with their project to study the a-c resistance and reactance of large conductors in steel pipe and conduit, the Insulated Power Cable Engineer Association laid out a series of conditions under which measurements were to be made of four types or sizes of insulated conductors. This series originally consisted of measurements to be made under isolated conditions in air (single phase); with three conductors cabled as in a 3-phase installation, though in air; and finally with three cabled conductors pulled into various sizes and types of conduit or pipe.

This paper records experiences with problems which arose in connection with these measurements and the methods by which the difficulties were resolved. The four major problems covered herein are:

1. Can the in-phase (resistance) component of measured voltage drop along individual conductors be used for the computation of power loss as an I^2R loss?

2. What is the significance of the wide differences among the measured values of resistance for the individual conductors in 3-phase tests?

3. How should the potential leads, for measurement of IR and IX drops along the conductors, be brought away from the cable to the potentiometer?

4. Can the component losses due to the several elements be measured or evaluated?

The resolution of problem (3) led to an examination of losses set up in neighboring conducting and magnetic materials and the methods of eliminating or evaluating such losses.

The potentiometer circuit used in making the measurements is described in some detail as having some value for future reference. The results obtained are examined not only for the resolution of the problems enumerated, but also for certain minor problems. For example, do the a-c resistance and reactance change with the measuring current, over the range of currents used for the measurements?

Previous experience in a-c resistance measurements[1] indicated that lengths of about 25 feet should be satisfactory. Accordingly the conductors, each insulated with 0.125-inch of dry paper and finished with a serving of friction tape, were cut into pieces 28 feet in length and copper lugs attached at each end. The central 15-foot portion of each length was designated as the test section and potential points were established with that separation. At each potential point a hole was drilled through the insulation and into the conductor to a depth of about 3/8 inch. This hole was then tapped and an 8/32-brass machine screw was screwed down tightly into the thread. When conductors were set up for test, potential leads were then soldered to the heads of these screws.

Test Methods

When arranged for single-phase measurements, two test conductors were set up to form the opposite sides of a rectangular loop. The fall-of-potential along each conductor between the potential points was measured in terms of resistance and reactance drops by means of an a-c potentiometer, with resistance and mutal inductance, connected in the secondary circuit of a current transformer, the primary winding of which was connected in series with the conductor being measured. A schematic diagram of the general test circuit in this application is shown in Figure 1.

The use of this potentiometer arrangement makes it possible to determine the equivalent resistance and reactance of the conductors directly in terms of a standard resistance and standard mutual inductance. When the following symbols are used:

T = current transformer ratio
M = setting of mutual inductor, henries
S = standard resistor, ohms
P = total resistance of potentiometer, ohms
N = resistance of that portion of the potentiometer inserted to obtain a balance, ohms
K = tangent of angle introduced by current transformer
W = angular velocity, radians per second

the relations expressing the effective resistance, R, ohms, and reactance, X, ohms, of the length of conductor under investigation are:

$$R = \frac{1}{T} \cdot \frac{SN}{S+P} - \frac{WMK}{T}$$

and

$$X = WL = \frac{WM}{T} + \frac{K}{T} \cdot \frac{NS}{S+P}$$

Naturally, the measured reactance is dependent upon the loop formed by the potential connections. Figure 1 indicates that several arrangements were used in the full conduct of these tests. Reactance values for single-phase operation were reported, however, only for measurements made with the potential connections tightly bound against the surface of the conductor insulation. These values then are reported as the 60-cycle reactance "to the surface of the insulation."

Since the reactances measured generally were of the order of twice the resistance, the use of current transformers with phase angles not larger than three minutes

Paper 48-249, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted April 9, 1948; made available for printing August 17, 1948.

E. H. SALTER is a research engineer with the Electrical Testing Laboratories, Inc., New York, N. Y.

Figure 1. Schematic diagram of connections for a-c resistance and reactance measurements under single-phase load

of arc ($K = 0.001$) makes the last term of each of these expressions negligible. The relations then become:

$$R = \frac{1}{T} \cdot \frac{NS}{S+P}$$

$$X = \frac{WM}{T}$$

which are the equations used in the determination of effective resistance and reactance in these measurements. The use of a reflecting galvanometer of the electrodynamometer type, with the fixed coil excited through a phase-shifter, made it possible to balance the potentiometer to better than ±0.1 per cent.

By means of a heavy-current switch, a change could be made quickly from the a-c potentiometer to a d-c double bridge, with suitable current source, for the measurement of the ohmic resistance of the conductors. The use of a suitable reflecting galvanometer with the Kelvin bridge made it feasible to measure these resistances to better than ±0.1 per cent.

The arrangements for 3-phase measurements followed the same general pattern as for single phase. Naturally, three test conductors were used for each 3-phase setup and these were connected together at one end to form a Y or star load on the supply. Currents then were adjusted to approximate a balanced condition and again measurements of fall-of-potential were made of each conductor in terms of the current in that conductor and the results averaged. The connections used are shown in Figure 2. Computation from individual balance indications then yield effective resistance, ohms, per phase and reactance, ohms, per phase, line to neutral.

Measurements were first made with the conductors at or near room temperature using only sufficient current to obtain the desired sensitivity of balance. Temperatures above room temperature were obtained by operating the cable under load until a steady-state condition had been established, and then making the desired observations at that current. From 8 to 16 hours was allowed to reach this steady temperature condition.

When working at room temperature it was the practice to measure the d-c resistance before and after each set of a-c measurements and the results were averaged. At temperatures above room, measurements of d-c resistance were made after the a-c measurements only. In this latter case, the usual practice of noting the time at each of a series of repeated observations made it possible by extrapolation to determine the d-c resistance corresponding to the time of opening the a-c circuit.

Figure 2. Schematic diagram of connection for a-c resistance and reactance measurements under 3-phase load

Accuracy of Resistance Measurements

Quite early in this work difficulties in interpreting some of the results obtained in the 3-phase measurements brought the accuracy of the measurements into question. Two series of tests therefore were conducted to demonstrate the degree of precision that might be expected in measurements made by the method described.

In the first of these checks a 4-terminal standard resistor, which had been constructed in 1910 for alternating current use and had been subject to periodic calibration since that time, was inserted in the heavy-current circuit in series with one of the conductors, and its resistance determined by the potentiometer method. Two sets of measurements were made in this manner, one in the single phase setup and another when arranged for 3-phase measurements. These results are shown in Table I.

This check showed a probable maximum error of the same general order as the limit of balance of the potentiometer, since in these measurements the potentiometer balance readings were 133.1 and 133.2 ohms, respectively.

A second series of checks, fundamental in its implications, made under 3-phase operation, compared the computed losses in the three conductors, using the potentiometer determinations of resistance, with the losses as measured by wattmeter methods. For these measurements a reflecting-type dynamometer wattmeter was employed. Determinations were made first by the 2-wattmeter method, and then by the 3-wattmeter method. Instrument limitations made it possible to observe these wattmeter indications

Table I. Check of A-C Standard Resistor

Assigned value of standard	0.00010073 ohm
A-C potentiometer measurements	
In single-phase circuit	0.0001008 ohm
In 3-phase circuit	0.0001009 ohm
Indicated maximum error	0.2 per cent

only to ±1 per cent. The results are shown in Table II. Here again the measured and computed values are in agreement to within the limit of observation. These two series of tests led to the conclusion that the a-c potentiometer method as used was giving a probable accuracy at least as good as ±0.25 per cent in the measurement of a-c resistance.

Interpretation of Individual Conductor-Resistance Measurements in 3-Phase Tests

Table III, which gives the results of a typical 3-phase test, shows a wide difference between the resistance balance indications of the a-c potentiometer for the individual conductors making up the 3-phase system. Such apparent differences in the resistance of the three conductors making up the circuit were found in practically all 3-phase measurements, regardless of whether the conductors were in air or in conduit. It was just such differences which originally raised the question of accuracy of measurement. When the accuracy of measurement had been demonstrated, the question still remained as to just what caused this unbalance in a-c resistances.

Those in contact with the investigation made numerous suggestions as to possible causes of the apparent differences and each was investigated.

Chief among the suggestions were the possibilities of stray-field pick-up in the measurement circuit, actual current unbalance in the system, and the manner of making potential connections. A careful survey for stray-fields which might influence results led only to several minor modifications in the disposition of the measurement circuit and did not serve to modify the test results. Currents in the system purposely were unbalanced by as much as 20 per cent with a negligible effect on the measurements. The method of making potential connections was modified to provide contact with a greater number of the individual strands, but no difference in measured values could be attributed to this modification.

Finally, the suggestion was offered that the apparent differences in measured resistances might be due to mechanical dissymmetry between the several conductors as arranged for test. This theory suggested that a small dissymmetry in the arrangement of conductors would result in sufficient distortion of the field pattern surrounding individual conductors to give a pickup in the loop represented by a conductor and its potential leads and to cause the resultant apparent resistance differences. This theory was therefore checked by experiment and the results contained are shown in Table IV.

Table II. Comparison of Measured and Computed Loss

	Watts
Computed loss in test section	59.0
Measured loss in test section	
2-wattmeter method	59.5
3-wattmeter method	59.0

These measurements showed definitely that an additional dissymmetry in the placement of these conductors in the triangle for 3-phase measurements would cause additional unbalance in the apparent resistance of the individual conductors, but it had a negligible effect on the total measured loss or on the average resistance of the conductors. It was concluded therefore that such accidental dissymmetry was the initiating cause of this apparent unbalance, but that its effect on the resulting average resistance, determined by the method being used, was of no appreciable consequence.

Examination of the d-c resistance values shown in Table III will indicate that the three conductors heated fairly uniformly under load. The a-c resistances for individual conductors as computed from the potentiometer readings are therefore only apparent resistances and do not truly reflect the division of the losses among the individual conductors, though their average value under a given condition is the true average a-c resistance.

Influence of Disposition of Potential Leads on Resistance Measurements—Single Phase

For the purpose of obtaining information which might be used in breaking down the results of measurements in conduit into component influences and to demonstrate that the conductors used were normal as to the usually computable losses, it was desirable to make certain single-phase measurements in air. These measurements were to be made first of an isolated conductor, free from proximity effects due to other conductors, and then at various distances from a similar conductor in order to evaluate the proximity effect.

When arranged for the first condition, potential leads were carried back from the potential taps, along the surface of the conductor under study, to the approxi-

mate center of the test section and from this point were taken as a twisted-pair to the potentiometer measuring circuit. The plane containing the loop formed by the potential leads from a conductor and that conductor was in each case made perpendicular to the plane containing the loop formed by the heavy-current circuit through the conductor being tested. However, when the conductor under test was gradually brought closer to the other side of the loop, to determine proximity effects, it was found that measured a-c resistances began to decrease and at a spacing of six inches between conductors the measured resistance was several per cent lower than that for a spacing of four feet and was still decreasing.

This apparent decrease in resistance was contrary to the usually accepted theory and hence directed some question at the measurement. Accordingly, a second arrangement was made in which the potential leads were first carried perpendicular to the conductor for a distance of two feet, and then the loop completed by carrying these leads parallel to the conductor to a point opposite the center of the test section and from that point by twisted-pair to the measuring circuit. Again the plane of the loop of the potential leads was made perpendicular to the plane of the loop of the heavy-current circuit. Using this arrangement, measurements were made at various conductor spacings from conductors in contact to four feet between centers. Figure 3 shows results typical of such a series of measurements.

It will be noted that under this arrangement the a-c resistance ratio first decreases sharply as the conductor spacing is increased, reaches a minimum at a spacing of about ten inches and then increases with spacing. The decreasing portion of this curve is typical of what might be expected in the way of proximity effect, but the increase with increased spacing would not appear to be a conductor effect at all. To demonstrate, another potential circuit arrangement was used at the four-foot spacing; in this case the plane of the loop of the potential circuit was made to coincide with that of the current loop and the potential leads were carried to the center of this loop before running parallel to the conductors. In this position the potential circuit loop intercepted the full flux of the current loop. At this spacing the indicated a-c resistance was found to be much greater than with any other loop arrangement.

These tests were conducted in a steel-frame building with the test conductors in a plane only about two feet above the reinforced concrete floor slabs. The apparent added resistance under these latter conditions was no doubt due to the losses created by the test circuit in the building structure. However, it is of interest to note that, even though the four-foot loop was inducing losses in the building structure, these losses were measured only in proportion as the flux threading this structure also threaded the potential circuit loop. When this loop was closed by binding the potential leads onto the conductor, the external losses were not measured. When the potential was opened to avoid the effects of field distortion at close spacing of the conductors, maintenance of this same arrangement of potential leads at wider conductor spacings allows this loop to link with flux which enters the building structure and produces an apparent increase in measured resistance. The ultimate was reached with the final arrangement, when all flux linked the potential circuit loop.

The true variation of conductor resistance with conductor spacing is probably that shown as a dotted curve, tangent to the two other curves at their extremities.

As a check, one member of the advisory group suggested making the measurement of increase in resistance due to skin-effect by wrapping the potential leads spirally around the conductor. This method was tried and the results are shown in Table V. Here it was found that wrapping the potential lead with a left-hand lay gave values quite different than obtained when the wrapping was given a right-hand lay. The average of the two measurements, however, was found to be in good agreement with results obtained with the potential connections bound to the conduc-

Effect of Method of Connecting Potential Leads to Conductors Laid in Conduit—3-Phase

When three conductors were set up in conduit for 3-phase testing, the question again arose as to what procedure should be followed in bringing out potential connections. As in the case of 3-phase measurements in air, the three conductors were laid together in such fashion that the driven potential taps on the individual conductors lay in planes perpendicular to the axis of the cabled assembly. Individual potential leads were brought out from each potential tap.

For measurements in air, these potential leads had been brought away from the cables, for a distance of about 24 inches, perpendicular to the axis of the cable. At this distance the leads had then been carried parallel to the test conductor toward the center of the test section where mate pairs were twisted together and led away to the measuring circuit. To follow this same procedure when the conductors were placed in conduit meant bringing these leads out through holes in the conduit (the 15-foot test length of conductors was centered longitudinally in the 20-foot length of conduit). The question arose as to whether bringing the leads through this magnetic circuit (iron conduit) would in any way give a linkage that might affect the results.

To check this the first conductors set up in conduit were provided with two sets of potential connections. One set was brought out through holes in the pipe as described before and the other set was carried along the conductors to the ends of the conduit and thence out. Two sets of

Table VII. Analysis of Transient Temperature Rise Data to Determine Power Loss Resident in Conduit

Condition	After 15 Minutes Operation	20 Minutes Operation
Conduit temperature (centigrade) rise with a-c heating		
26.4 watts per foot, cable	0.65	1.0
28.2 watts per foot, computed	0.7	1.05
Conduit temperature (centigrade) rise with d-c heating		
28.2 watts per foot (cable)	0.2	0.35
Incremental temperature (centigrade) rise		
28.2 watts per foot (cable)	0.5	0.7
Conduit temperature (centigrade) rise with self heating		
9.4 watts per foot	1.9	2.35
Computed watts per foot self heating in conduit with 28.2 watts per foot delivered to cable	2.5	2.8
Relative value of watts self heating in conduit as per cent of total power delivered to system	9	10

Figure 5. Typical test results. 1,500,000 circular mil concentric strand conductors, triangular arrangement, 3-phase, 1.70 inch spacing, in air

observations were made, one for each system of potential leads. The individual conductor measurements for the two systems were widely different, but again the average values obtained were in close agreement. The data obtained using the leads brought out through the holes in the pipe showed variations between individual conductors which were comparable with those obtained for the conductors in air, but when using the leads brought out at the ends of the pipe the spread between individual values was much greater, one conductor even indicating a negative resistance in this case.

Based on these findings all of the tests in conduit or pipe were made with potential leads brought out through holes in the pipe.

Effect of Current Magnitude on Measurements of A-C Resistance in Conduit—3-Phase

The various cable temperatures obtained for test conditions in this investigation were produced by circulating current through the conductors as arranged for test. Measurements then were made with this value of heating current in order to assure stable temperature conditions during this measurement process. As a result each test point was taken under a different current loading condition. This naturally raised the question as to what variation might be expected due to the magnitude of the test current and whether this might have to be taken into consideration in arriving at the final results. This was especially questioned where tests were run in conduit which might saturate magnetically and thus influence results. Tests to determine the magnitude of such influence were run and the results are shown in Table VI.

The general conclusion indicated was that current magnitude has a relatively small influence on the a-c resistance value compared to the influence of temperature and hence can be neglected in analyses of these measurements.

On the other hand, it is indicated that probably most of the change in reactance found is a function of current magnitude rather than of cable temperature. However, the change in reactance with current in many tests was found to be quite negligible and amounts to only a few per cent in any instance.

Separation of Losses in Conduit from Total Losses

In the analysis of these data it became desirable to separate the total losses into the losses in the conductors and those in the conduit. This was done from comparative time-temperature studies of the conductors and of the conduit under the transient heating of cable and conduit immediately following: a-c loading of the cables; d-c loading of the cables; and d-c heating of the conduits. Under the second condition it is evident that all of the heat was generated in the conductors themselves, while in the third, all of the heat was generated in the conduit.

This study was made using three 2,500,000 circular mils concentric-strand conductors arranged in the conduit in the same manner as for the a-c resistance measurements. Spot temperatures of both conductors and conduit were measured with copper-constantan thermocouples in conjunction with potentiometer-type temperature indicators arranged for use with box-type reflecting galvanometers to give a sensitivity of about 0.2 centigrade. Six thermocouples were laid against the individual copper conductors, and covered with the paper insulation, distributed between the three conductors at two locations about ten feet apart. Another six couples were

Figure 6. Typical test results. 2,500,000 circular mil concentric strand conductors, triangular arrangement, 3-phase, 2.17 inch spacing, in 6-inch conduit

bound to the surface of the insulation of these conductors. Eight thermocouples were attached to the outer surface of the conduit by means of Scotch tape, these being distributed both laterally and circumferentially. A mercury-in-glass thermometer was likewise placed in contact with the outer surface of the conduit.

Average temperatures were obtained from resistance measurements. Such measurements were made of the conduit in all tests and of the conductors also in the case of d-c tests. In the a-c tests the normal measurements of a-c resistance were made.

A reference body for ambient temperature was supplied by another length of conduit supported at the same level as the test conduit and about 18 inches away. The temperature of this body was measured in the same manner as for the test conduit.

The tests were run with a timekeeper and five observers. Three observers made the temperature determinations with the thermocouples, while the other two measured resistances. Readings were taken at definite times in order to co-ordinate the results. Observations were made in groups, at 20-second intervals, and 12 sets of readings were taken during the first hour of heating.

From these data the temperatures of the conductor and of the conduit were computed for the various times. Temperature rises then were determined, making due allowance for change in the reference conduit. Using the data from the three different heating conditions, each run with a known rate of energy dissipation, it was possible to compare conduit temperature rise during the first 15 to 20 minutes of heating and thus arrive at a proportionate division of the heating under a-c operation. These analyses led to the conclusion that for three 2,500,000 circular mil concentric-strand conductors in triangular arrangement, with 2.17-inch spacing between conductor centers, laid in six-inch iron conduit, 9 to 10 per cent of the total a-c losses was generated in the body of the conduit. Table VII shows the steps of this analysis.

Typical Test Results

After a method had been established for making these measurements a series of conditions in air and in conduit was set up for each conductor investigated. While an analysis of these results is being made in other papers presented at this meeting, it seems appropriate here to present typical test results. Figures 4, 5, and 6 are typical of the three types of tests conducted. Smooth curves were prepared for each test arrangement and the data for analysis have been taken from these curves.

1. Resistance and Reactance of 2-Conductor Cables, E. H. Salter, G. B. Shanklin, R. J. Wiseman. Electrical Engineering (AIEE Transactions) volume 53, 1934, December section, pages 1581-9.

Discussion

L. F. Roehmann (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): Salter's paper is an excellent presentation of difficulties and perplexing results which may be encountered by any electrical engineer engaged in experimental work. I was pleased because usually difficulties of this kind are glossed over or entirely omitted in a discussion while here they form the basis of the paper.

As I see it, Salter and his sponsors wrestled fundamentally with the following three questions:

1. When a heavy conductor carrying alternating current is brought into close proximity to some metal, for instance to another conductor, why does its a-c resistance increase? And subsequently: when three conductors of a 3-phase system are brought into close proximity, how does the a-c resistance of the individual conductors change, and of their sum?

2. Does the arrangement of thin potential leads (which carry no current) affect the a-c resistance of an isolated conductor?

3. When a cable carrying alternating current is installed in a metallic pipe, how can the pipe losses be determined?

By emphasizing the energy concept, I believe these questions can be answered without too much difficulty.

Question 1. When metal is brought into an a-c field, for instance into the field around a straight conductor, it will be heated due to induced voltages and currents. Without metal in proximity, the conductor draws, and dissipates, a certain amount of energy, equal to I^2 times R_{ac}. With metal in proximity the total energy drawn from the source increases. It is equal to I^2 times an increased R_{ac}. This entire energy is not expended in the conductor. Part is handed on to the metal and expended there. This is nothing but the well known transformer. The energy input at its primaries is not expended within the transformer—this would be zero efficiency, but is essentially handed on to the connected load. A conductor with some metal nearby is of course a very inefficient transformer, but still its efficiency is not zero. Part of the input energy is handed on and the a-c resistance at the conductor (but not of the conductor) increases.

In case of three conductors of a 3-phase system, each conductor can be considered as a primary, inducing currents (that is, losses) in the two neighboring conductors. Spacing, obviously, plays an important role in the amount of energy transferred and consequently affects the a-c resistance measured at (but not of) each individual conductor. While in the first case the energy is actually handed on to an outside consumer, we have now an intra-conductor play, so to speak. No energy is transferred to the outside. As a consequence, the sum of the three a-c resistances remains constant, however different the individual resistances may be.

Question 2. Considering an isolated conductor carrying alternating current, its resistance should be unaffected by position and location of the leads. Any such variation would be contrary to the energy concept. Theoretically, currents will be induced in the leads because they are made of metal. Practically such losses will be immeasurably small for lead wires whose cross-section is small as compared with the conductor under test. Hence, if variations were observed, they are caused by other effects.

Our laboratories are housed in a wooden structure, and all services were carefully kept away from our current laboratory. Tests made in it showed no variation in a-c resistance for different lead arrangements. No question that the variations found by Salter are caused by the steel in the reinforced-concrete floor which was only two feet below the conductor under test.

Question 3. Conduit losses were determined by Salter but in a fairly round-about manner. The discusser has used, in 1943, a simple method as follows (for single conductors):

a. Bring twisted potential leads through a hole in the conduit, spread them apart inside, connect to cable, and measure R_a, Figure 1 of the discussion.

b. Bring twisted potential leads up to pipe, spread them apart outside, take through two holes in conduit, connect to cable, and measure R_b.

c. Calculate conduit loss as $I^2 (R_a - R_b)$.

This procedure is straightforward, and in addition, pedagogically interesting. In both cases the a-c resistance *at* the conductor is measured but only in connection (a) the resistance *of* the conductor. Connection (a) determines the energy expended in the conductor, and connection (b) the energy expended in conductor plus pipe. Obviously the difference is directly the pipe loss.

E. E. Hutchings (British Electrical and Allied Industries Research Association, London, England): Referring to the four major problems specified on page 1 of Salter's paper.

1. The measured a-c resistance will differ as between the individual cables of a 3-phase system if these are not symmetrically ar-

Figure 1. Lead measurements for measuring pipe losses (one conductor)

ranged, owing to phase transference of power through the magnetic field.[1] This has no influence on the heating, which is equal in all three cables. For balanced currents, the total losses are given by $3I^2R$, where R is the mean value of a-c resistance in the three cables.

2. The difference in measured value of a-c resistance between the individual conductors is in part due to the phase transference of power referred to in 1. and in part to asymmetry of the conductors with respect to adjacent metalwork.

3. The ideal method of running potential leads for such measurements as are described in the paper is to locate any portion of such leads which is parallel to the cables at an equal distance from each of them. In practice, this may be done by running leads back from the star point of the conductors at a distance from them of not less than 50 times the distance between their centers, since the magnetic field due to the three cables at such a distance is negligible.[1] In similar tests made by the British Electrical and Allied Industries Research Association, the potential leads were run from 15 to 20 feet above the cables. The symmetry of the arrangement of current carrying conductors can be checked by passing single-phase current through two of them and measuring the potential induced in the third and its potential leads, which should be negligible in comparison with the volt drop along this conductor when it is loaded. The results of Figure 3 of Salter's paper can be attributed to a nonsymmetrical disposition of the potential lead in relation to the two current carrying conductors. The normal variation of proximity effect with spacing would be observed if this lead had been disposed as recommended above. The results given in test number 1 in Table I of Wiseman's paper[2] agree well with the theoretical calculation of skin effect, since in this test the spacing is such that proximity effect would be negligible. The additional increment of resistance due to the latter effect in test number 2 is, however, very much greater than would be expected on theoretical grounds at the spacing indicated. Proximity effect for three cables in triangular formation in air, closely spaced, is given to a close approximation[4] by the expression

$$y_1 = 1.5\ (d/s)^2 y$$

where

d = diameter of the conductor
s = axial spacing between conductors
y = increase due to skin effect.

4. The losses in the conductors in air, in the absence of adjacent metalwork, can be measured and compared with theory on well established principles.[1] Very close agreement has been obtained in tests, similar to those described in the papers, which were carried out by the British Electrical and Allied Industries Research Association.[5] The increase in resistance due to proximity to steel in the form of plates parallel to the conductors is less than 0.002 microhm per centimeter at 12 inches from the steel for closely spaced conductors (as in a pipe) and is independent of conductor size.[6] This is less than 2 per cent for the largest conductors considered in the AIEE papers. The excess losses when the conductors are run in a steel pipe can be compared with theoretical values calculated as for steel armoured cables by known methods[7] using the appropriate properties of the steel. Only an approximate value need be assigned to the permeability, since variation of this over a wide range has but little effect. Unfortunately, only the nominal diameter of the pipes and their resistivities are given in the present papers: full dimensional data are required in order to check the experimental results against the theory.

E. H. Salter: The problems discussed in this paper arose in an investigation to determine the circuit constants of certain large conductors operated as a 3-phase transmission system in iron pipe or conduit, and in the experimental analysis of certain of these findings. Definite limitations were placed on the extent of the investigation due to the problem of defraying the costs.

Measurements were made of only four sizes or types of cable under current loadings covering the range indicated in Table VI. Here the lowest current load in each case was that required to give adequate sensitivity in measurement and the other values were the load currents required to give heating to produce the conductor temperatures as shown in Figures 4, 5 and 6. The purpose of Table VI then is to show that measurement at these various currents did not influence conductor characteristics over the temperature range investigated.

All measurements of conductors in pipe were made with the pipe insulated. No attempt was made to determine voltages that might have appeared along the pipe. Since measurements were made by potentiometer using an a-c galvanometer as a detector, any harmonics which may have appeared due to nonlinearity of the magnetic circuit did not enter into balance conditions.

The suggested analysis of some of the measurement problems by emphasizing the energy concept serves only to reiterate the analysis in the paper of the influence of disposition of potential leads on resistance measurements, single phase. In addition to energy losses in neighboring metal structures, it becomes necessary to take into consideration changes in current distribution in a conductor due to internal reactions (skin effect) and to the flow of current in other near-by conductors (proximity effect), which in each case affect the resulting a-c resistance. Then too, in 3-phase measurements any loop provided for measurement of one conductor has linkage with flux from the other two conductors as well. Since the currents in these other conductors are out of phase with the current in the conductor under measurement, such linkages may give in-phase or resistance components to the measured drop. Only when the potential loop is made to extend a considerable distance from the conductors will the fields of the three conductors effectively neutralize and the resultant of these in-phase components be at a minimum. Accuracy of measurement would dictate that the truest average is obtained when each of the three observations is closely alike. If in 3-phase measurements, the potential leads were carried back close to the conductor group this would not be the case. Hence in all 3-phase measurements the potential leads were brought out at least 24 inches away from the cables and then carried parallel to the group to close the loop.

The suggestion for measurement of conduit losses would be subject to this same criticism. Any measurement made with potential leads forming a loop inside the conduit would give a doubtful measure of energy expended in the conductors of a 3-phase system, due to the close proximity of the small potential-circuit loop (thus formed) to the individual conductors and to the failure of fields to neutralize at that distance

Military Teletypewriter Systems of World War II

F. J. SINGER
MEMBER AIEE

THE TELETYPEWRITER was a vital communications tool of World War II. Secret teletypewriter communications to permit close and efficient coordination between all echelons, from comparatively small tactical units to the highest military and diplomatic leaders, were handled with accuracy and dispatch on a very efficient basis. Wire and radio teletypewriter networks, extending over land and sea were used intensively by our armed forces and Government officials for handling the stupendous tactical, supply, and administrative problems, as well as the affairs of state, brought about by the war. These teletypewriter communications became a reality as a result of the development since late 1941 of improved teletypewriter cipher arrangements and of means to permit dependable teletypewriter operation, not only over short-haul radio and military wire-line networks, but also over transoceanic and other long-haul radio circuits.

This paper reviews the evolution of military teletypewriter communications since 1941 and briefly describes some of the important systems that were developed during the war by Bell Telephone System engineers for the armed forces.

Telegraph Communication Systems as of 1940–41

Commercial Wire-Line Systems in the United States

Immediately prior to the Pearl Harbor attack the large amount of commercial and the relatively small amount of military telegraph communications within the United States were handled mostly over wire lines. Teletypewriter, rather than manual keying methods, were used in the majority of these communications. Through successive improvements made in teletypewriter apparatus[1] and in the d-c[2,3] and carrier telegraph[4,5] line facilities since World War I, it was practicable to send several teletypewriter messages simultaneously over long wire-line circuits at speeds of 60 words per minute and higher.

The Western Union Telegraph Company and Postal Telegraph Company utilized teletypewriters for communications between their local offices and main distributing centers in each city. These companies passed their intercity public message and their large customers' leased circuit traffic over carrier and d-c telegraph channels generally using either synchronized time-division multiplex telegraph methods[6] or variations of this method,[7,8] thereby obtaining very efficient use of the line facilities. With synchronized time-division multiplex, commutating devices provide a means whereby two or more messages are sent over a single telegraph channel.

The Bell Telephone System furnished teletypewriter exchange (*TWX*) [9,10,11] and private line manual Morse and teletypewriter[11,12] services, providing direct communication between two or more stations in each customer's connection or network, as is done in telephone service. With direct connections the sender's message is recorded at all customers' offices in the network as soon as the message is sent.

Paper 48-251, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18–22, 1948. Manuscript submitted Feb. 26, 1948; made available for printing August 17, 1948.

F. J. Singer is switching development engineer with the Bell Telephone Laboratories, Inc., New York, N. Y.

The Bell Telephone System and telegraph companies also furnished private-line switched teletypewriter service on a leased network basis[11,13,14] to some of the large users of teletypewriter service. This form of service permits a very rapid handling of messages and a high traffic-carrying capacity of the intercity trunks used in the network.

Overseas Telegraph Systems

Prior to the war telegraphic communications between the continental United States and foreign countries were handled by radio and submarine cable. Traffic was handled on an efficient basis over high-speed submarine cables[15] using the synchronized time division system.[16] The long-haul radio links employed international Morse code methods generally using perforated tape sending and dot-dash inked tape receiving.[17] With this tape method it is necessary to read the receiving tape and translate the information manually into typed messages. Teletypewriter methods[18,19] were applied only to a minor extent over long-haul radio because of transmission difficulties.

Systems Used by the Navy

The Navy operated a rather extensive network between shore stations, between ships and between ships and shore. Practically all of the Navy traffic was handled by manual international Morse code telegraphy. The Navy had not adopted the teletypewriter although to care for large traffic over their main communication routes they used the perforated-tape-sending and inked-tape-receiving method of transmitting international Morse code signals. Skilled operators and reasonably good radio paths were required and the latter were not always available. It was, of course, necessary to transcribe manually incoming dot-dash messages at the receiving end of the circuit

Systems Considered by the Army

Because of restrictions imposed by peacetime conditions the Army used only a relatively small amount of wire-line teletypewriter communications facilities within the United States. These condi-

Figure 1(a). Teletypewriter set, *EE-97-A*

Figure 1(b). Application of teletypewriter set, *EE-97-A*

Figure 3(b). Typical connecting circuits to telegraph central office set *TC-3*

tions made it very difficult for the Signal Corps to do more than consider potential communication networks for war purposes. At the beginning of World War II the Signal Corps had worked out comprehensive plans for handling wire-line telegraph and teletypewriter communications. Work had been done in co-operation with the Teletype Corporation engineers and other groups toward the development and production of portable military teletypewriter equipment. The trend at that time indicated, however, the use of slow manual Morse methods and not teletypewriters over radio.

Evolution and Advantages of Cipher Teletypewriter Systems for Military and Diplomatic Communications

During World War I Bell Telephone System engineers recognized the advantages of the teletypewriter as a particularly suitable means of providing military and diplomatic communications. Indeed it was during this period that they developed the method of locally enciphering and deciphering teletypewriter signals.[20–24]

With the advent of World War II it was natural for the Bell Telephone Laboratories and Teletype Corporation engineers to advocate the use of ciphered teletypewriter arrangements in military and diplomatic communications. With close co-operation of the Army, modernized teletypewriter enciphering and deciphering arrangements were quickly developed not only for local but also for direct on-the-line usage in which ciphered messages are handled with practically the same ease and speed as plain text messages. The Army started to apply both arrangements soon after Pearl Harbor.

Teletypewriter cipher communication methods have the outstanding advantages of secrecy, dependability, ease of training operators, speed in handling messages, and of accurate and efficient use of the transmission medium. Ordinary telegraphy, coded words of speech and other cipher systems do not have all of these advantages. The advantages of cipher teletypewriter communications were generally recognized by the War and Navy Departments and by the other departments of the Government and their use over both wire and radio networks rapidly became the backbone method of military communication during World War II, especially where long distance communications were involved and where conference connections were desired.

Figure 2. Reperforator teletypewriter set *TC-16*

-C and Carrier Telegraph Systems for Wire Lines Used in World War II

It was recognized at the outset of World War II that military wire-line telegraph systems must be capable of withstanding extreme and widely fluctuating tempera-

Figure 4 (left). Telegraph repeater TG-30 (Terminal)

Figure 5. Telegraph repeater TG-31 (Intermediate)

ture and humidity conditions, must be sufficiently rugged for transportation at least into and through the theatres of operation if not in combat areas, must be capable of operating from a-c sources of power supply whose voltage and frequency fluctuate considerably, and must be capable of being set up for operation in a very short time and of operating over long periods with a minimum amount of maintenance. These engineering problems were quickly and successfully solved and during 1942 some of the first military wire-line telegraph systems were delivered to the Army. Constant progress was made after that date and the armed forces were well supplied with up-to-date military d-c telegraph and wire-line carrier telegraph equipments for handling their teletypewriter and other telegraphic communications. The engineering problems were attacked and solved, having in mind that all of the components used in these military teletypewriter communication circuits had to fit into and be a part of a complete working system, each component forming a link in a chain. The approach is sometimes called the "system's viewpoint" and is the method which is followed in planning and engineering American *TWX* and private line teletypewriter networks.

Military D-C Telegraph Arrangements

In the military d-c telegraph field some of the important units, used by our armed forces to handle teletypewriter communications in the theatres of operation, made by various manufacturers, are:

*Teletypewriter Set EE-97-A**. This set includes a page-receiving and keyboard-sending teletypewriter, coded *TG-7-B*, which is arranged for operation at 60 or 66 words per minute. It also includes line unit *BE-77* and power equipment. Figure 1(a) shows teletypewriter set *EE-97-A* and Figure 1(b) is an illustration of how it was used over short wire-lines. It is used also in carrier telegraph and radio teletypewriter networks.

*Reperforator Teletypewriter Set TC-16**. This set includes reperforator transmitter *TG-26-A*, line unit *BE-77-A* and a power supply unit. Reperforator transmitter *TG-26-A*, perforates and types messages on a tape from a local keyboard or from line signals and sends signals from tape run through the transmitter at either 60 or 66 words per minute. Reperforator teletypewriter set *TC-16* was connected in the same general manner as teletypewriter set *EE-97-A* to d-c telegraph wire-line circuits, and to carrier and radio teletypewriter circuits. Figure 2 is an illustration of this set.

*Telegraph Central Office Set TC-3**. This set includes a 10-line teletypewriter switchboard, coded *BD-100*, a *TG-7-B* operator's teletypewriter and power supply equipment. The *BD-100* switchboard provides a means of interconnecting wire-line and radio teletypewriter circuits manually for either point-to-point or conference connections. Two or more *BD-100* switchboards were operated together to increase capacity. Figure 3(a) shows the telegraph central office set *TC-3* and Figure 3(b) is a schematic of a typical network including other tactical equipments.

Repeater TG-30, Repeater TG-31, and Repeater Package X-61824A. The *TG-30* and *TG-31* repeaters are combat types and the *X-61824A* package is a fixed plant type. All of these repeaters operate on a polarential[8] transmission basis. The *TG-30* and *X-61824A* provide means of operating teletypewriters over simplexed Army field wire up to 50 miles; by interposing a *TG-31* at the middle of such a circuit, operation up to 80 miles was possible. These repeaters could be used also on simplex and composite bases over cable and over much longer links of open wire. Figure 4 shows a *TG-30* and Figure 5 a *TG-31* repeater. Each cabinet includes a power rectifier for operation from a-c power. Figure 6 shows an *X-61824A* repeater package cabinet housing two repeaters with their associated power rectifiers.

Regenerative Repeater Package, X-66031A. This repeater provides a means of reconstructing teletypewriter signals after they have been badly distorted as a result of transmission over a telegraph circuit that is operated near its limit of transmission capability, thereby permitting a considerable extension of transmission range. Figure 7 shows a cabinet housing two of these repeaters.

Military Multichannel Carrier Telegraph Wire-Line Systems

The Army used two classes of multichannel carrier telegraph wire-line terminals in the theatres of operation, tactical and fixed plant. The tactical terminals, known as the *CF-2* and *CF-6* types, were used with the spiral-4 cable and also with Army field wire, with open-wire lines, and with commercial cable. The Army also used them with portable frequency-modulation radio sets to pro-

Figure 6. Telegraph repeater package, X-61824A (Terminal)

*These sets were developed by Signal Corps Laboratories. They were manufactured by various contractors and made use of teletypewriter apparatus furnished by Teletype Corporation.

Figure 9. Fixed plant military voice frequency carrier telegraph terminal X-61822

Figure 8. Military voice frequency carrier telegraph terminals

View showing physical comparison

vide multichannel teletypewriter circuits. There are two types of *CF-2* terminals; these are coded *CF-2-A* and *CF-2-B*.[18] Either type provides four 2-way teletypewriter circuits over a 2-wire circuit that is suitable for telephone. By supplementing either of these terminals with *CF-6-A*, a total of six 2-way teletypewriter circuits was provided over a 2-wire circuit. Where 4-wire telephone facilities were available, the number of teletypewriter channels could be doubled by using twice as much terminal equipment. The *CF 2-A* terminal was superseded by the *CF-2-B*, which is one-half the size and is about 55 per cent as heavy. Figure 8 shows a comparison in size and appearance of the *CF-2-A* and *CF-2-B* terminals.

In addition to the *CF-2* and *CF-6* types of carrier telegraph terminals, a so-called "packaged carrier telegraph system terminal" was provided for fixed plant use by the Signal Corps. This equipment makes use of the same apparatus components as those used in the *CF-2-A* but the over-all assembly is quite different both physically and electrically, as the packaged equipment was called upon to meet somewhat different service requirements than the tactical equipment. The package terminal is arranged for operation over a 4-wire telephone circuit and either 6 or 12 2-way teletypewriter circuits could be obtained over such a circuit, depending upon the amount of equipment used. Figure 9 shows the complete equipment of a 6-circuit terminal. For 12 circuits an additional pair of cabinets was required.

Figure 10. Teletypewriter networks in European theatre of operations, January 1945

Figure 10 illustrates the scope of the "fixed plant" teletypewriter networks in the European theatre of operations during January 1945; the tactical circuits in the forward areas are not included. The carrier and d-c telegraph equipments described previously were used in this network. The long-haul radio equipments are those described later in this paper.

Radio Teletypewriter Systems Used in World War II

The radio teletypewriter communication networks used by Government officials and the armed forces included a number of different systems which may be divided broadly into two general classes, short-haul and long-haul systems. The former class was generally used over relatively short distances up to about 200 miles with the maximum distance between radio repeater points not in excess of about 40 miles; the latter over long stretches of water or over difficult terrain where intermediate radio repeater points were impracticable. Each teletypewriter channel in these systems handled traffic at a normal rate of 60 words per minute and sometimes at higher speeds.

Short-Haul Radio Teletypewriter Systems

Short-haul radio teletypewriter systems that were developed by the Bell Laboratories during the war for the Army and Navy made use of telephone-type radio sets operated on either an amplitude or frequency modulation basis. Toward the end of the war it was also possible to establish radio teletypewriter communication links in the ultra high-frequency radio range by applying these short-haul radio teletypewriter systems to one or more of the channels in multichannel pulse modulation radio systems.[26] Certain of the short-haul radio teletypewriter systems were installed on a fixed plant basis and others were used on a combat basis.

An example of a fixed plant system is the Navy "carrier control system—model *UN*." This is a 1-way system capable of transmitting as many as 36 individual teletypewriter messages simultaneously. It was, and is still used mainly for interconnecting a naval headquarters control station and nearby stations where a number of long-haul radio circuits terminate. Figure 11 shows the over-all layout of a typical small sized installation and Figure 12 shows schematically the various service options and channel frequency allocations. The naval headquarters control station is located several

Figure 11. Carrier control system model *UN* for United States Navy. Typical arrangement in a naval area

miles from either of the long-haul radio stations which are separated from each other by several miles to avoid mutual interference. Originally intended as a fall-back system for emergency use in cases of failure of wire lines, the model *UN* system is being used satisfactorily in the Hawaiian Islands, and in the Washington, Panama, San Diego, San Francisco, Seattle, San Juan, and other areas in regular service. Bell Laboratories engineers designed the radio transmitters, receivers, and carrier equipment in this system, and also co-operated in the field in connection with their installation and adjustment. A somewhat similar system, coded *42B1*, was also developed for the Army. It came into use during the war to interconnect terminals of long-haul radio teletypewriter links and Army signal centers, such as between the radio station at Fort Myer, Va., and the telegraph central office—WAR—in Washington.

A portable short-haul multichannel teletypewriter system, which is known as the Navy "portable carrier control system—model *UF*," provides four teletypewriter channels in each direction over a 2-way radio link. The equipment may be landed readily on a beach and requires only a few minutes to set up for service. Figure 13 shows a schematic of a typical setup of the equipment of the model *UF* system. The line terminals and radio line terminal, shown in Figure 13, were ordinarily used in conjunction with a portable amplitude or frequency modulation *VHF*-type radio set for termination of a point-to-point multichannel radio teletypewriter circuit. The capacity of the system is four 2-way teletypewriter circuits, each operating at 60 words per minute.

Long-Haul Radio Teletypewriter Systems

The transmission of teletypewriter pulses over long-haul high-frequency radio was not accomplished, as might be supposed, merely by connecting the teletypewriter machines to radio facilities that were in use prior to the war. The prewar radio systems did not contain the features to overcome the effects of signal fading and other natural and man-made disturbances required for good teletypewriter service. The wide experience of Bell Telephone System engineers in the design of electronic circuits and in the development of land-line teletypewriter and radio telephone systems proved to be of great value in their efforts to surmount these transmission difficulties. With the co-operation of the Army and the Navy, the required features were developed during the early part of the war and applied to long-haul high-frequency radio to permit teletypewriter machines to receive enciphered radio teletypewriter messages with only an occasional error.

In the conventional single-channel long-haul radio telegraph system in general use before the war, the radio transmitter was keyed by manual or automatic methods using the international Morse code. With this method, the sending key controls the output of the radio transmitter; when the key is closed energy at a particular radio frequency is transmitted and when the key is open the transmitter is cut off. Reception of these signals is possible using a tunable amplitude-modulation radio receiver similar to those in homes. The listener reads the interrupted "tone" signals as "dots" or "dashes," or they are automatically recorded on a tape.

If the transmitting telegraph key is replaced by the sending circuit of a teletypewriter and a simple rectifier is interposed between the output of the radio receiver and the receiving teletypewriter, it is possible under favorable conditions to receive good teletypewriter copy. Frequently, however, the arrangement will be unsuitable.

In the single-channel long-haul *AN/FGC-1* system, shown in Figure 14 and developed during 1942,[22] a new device, known as a frequency shift keyer, is actuated by the open and close pulses produced by the sending teletypewriter apparatus. The keyer causes the radio transmitter to emit radio power at a particular frequency for teletypewriter open pulses and a slightly different frequency but the same power for the close pulses. In order to minimize some of the transmission difficulties experienced in many long-haul radio paths, such as the tendency for a radio wave to fade out at a particular spot but to be noted at another point close by, two separate antennas and two radio receivers are used, as shown in Figure 14. This is known as space diver-

Figure 12. Carrier control system, model *UN*, for United States Navy

Typical system layout and transmission bands

Figure 13. Carrier control system, model *UF*, for United States Navy

sity reception and, with antennas spaced a few wave lengths apart, fading out of the received signals is extremely unlikely to occur at both receiving points at the same time.[17]

Except during fading, when one radio receiver may become virtually inactive, each receiver delivers to the teletypewriter system a current of a particular audio-frequency when a teletypewriter open pulse is received and a current of a different audio-frequency when a teletypewriter close pulse is received.

Each channel of the teletypewriter terminal equipment includes a wide-band filter, a fast-acting current limiter, the input-output characteristic of which is shown in Figure 15, a filter and a detector *S* for the reception of teletypewriter open signals, and similar equipment for the reception of close signals. The output circuits of the two channels in the terminal will appropriately combine these signals to operate a polar relay, which, in turn, delivers d-c signals to the receiving teletypewriter apparatus.

By having the limiters in the receiving equipment continuously energized by the

Figure 14. Single channel frequency shift long-haul radio teletypewriter link using *AN/FGC-1* terminal equipment

Figure 15. Current limiter characteristic

frequency shift constant power radio transmitter, the effects of noise are overcome to a much greater degree than in the on-off keying method. When combined with space diversity reception the resultant system was found to be highly reliable. Often, when the tones are indistinguishable to the ear because of noise, the receiving teletypewriter continues to operate without errors.

The equipments comprising the *AN/FGC-1* system are arranged for rapid installation and, although somewhat large, were transported by airplane into advance points to meet urgent needs.

An alternative, but quite similar system to the one developed for the Army, and known as the *AN/FGC-1A* was designed and made available for use by the Navy at their large well-established shore station installations. Many of these are now being operated over routes such as Washington—Honolulu, San Francisco—Honolulu and Washington—Balboa.

In addition to the need for the single-channel long-haul *AN/FGC-1* system, during 1942 the Army also had a very urgent need for a high traffic-carrying capacity long-haul radio system to handle their written communication between Washington and major overseas headquarters. To care for this demand Bell Telephone System engineers devised a highly satisfactory long-haul multichannel radio teletypewriter system[29] making use of available single side-band twin-channel radio telephone[29,30] and carrier telegraph equipments together with additional components, such as fast-acting current limiters (Figure 15), that were needed to make the system suitable for reception of teletypewriter signals. The radio transmitters and receivers used in this system are the suppressed-carrier twin-sideband types that have been in use during the last several years in Bell Telephone System overseas telephone service. The multichannel carrier telegraph equipment is an adaptation of the type used extensively in Bell Telephone System carrier telegraph wire networks. By applying the carrier telegraph multichannel frequencies to one sideband of this system in such manner that two separate and distinct audio-frequency tones are supplied for each teletypewriter channel during the close-circuit condition and two other tones during the open-circuit condition, frequency diversity operation is provided. The use of two frequencies for each signal condition minimizes the effects of signal fading in a manner similar to space diversity operation described previously. Figure 16 shows schematically one terminal of this system.

The first of these systems was provided within a few weeks after it was requested and successful operation was obtained between Washington and London using one sideband of the existing radio telephone system to provide three simultaneous teletypewriter circuits in each direction. The capacity of this system was later doubled. The Army operated a number of these multichannel transoceanic links for many months in a highly successful manner between such points as Washington—London and San Francisco—Australia. The Navy obtained also a number of these systems for use over their main global communication routes, such as that between Washington and Honolulu. A common military application of this system included six telegraph channels applied to one of the sidebands of the twin-channel radio telephone system with the other sideband available for telephone. When used in this manner the system had a teletypewriter traffic-carrying capacity of about 5,000 100-word messages per day in each direction.

As a result of the phenomenal success of the *AN/FGC* type systems from the outset, both the Army and Navy became very much interested in obtaining smaller and lighter weight frequency shift keying systems. Small size equipments were particularly important to both services in connection with their contemplated large-scale use of long-haul radio teletypewriter circuits between points in rear areas and advanced bases and between shore stations and ships. As a result of this interest, during 1944 the Bell Telephone Laboratories undertook the design of smaller equipments. One of these was a new receiving equipment for use with a pair of amplitude-modulation radio receivers, designated Navy "model *FRF*

Figure 16. Multichannel radio teletypewriter system or single sideband twin-channel radiotelephone

frequency shift receiver converter equipment."

Field tests made by the Navy of an engineering model of this new equipment indicated that it performed better than the *AN/FGC* type though much smaller and lighter. More recently a large number of these equipments have been delivered to the Navy for use at both shore and ship stations. Figure 17 shows a physical comparison between the radio telegraph terminal equipment, *AN/FGC-1*, and the model *FRF* frequency shift receiver converter equipment.

The Bell Telephone Laboratories also developed frequency shift applique equipment for use with the truck-borne radio set *SCR-399-A* which was the Army's tactical work-horse among radio sets. This applique, designated radio teletypewriter equipment *AN/TRA-7*, permits the radio equipment to send teletypewriter signals on a frequency shift basis and to receive these signals on a dual space diversity basis. In addition to permitting 2-way or full duplex teletypewriter service, the *AN/TRA-7* equipment contains features to permit a new form of service, known as one-way reversible. With this service a to-and-fro teletypewriter communication can be carried on between two distant points using the same radio frequency assignment on an alternate basis for both directions of transmission. Figure 18 shows the arrangement of the *AN/TRA-7* equipment and other components comprising the complete radio sending and receiving equipments and teletypewriter operating center. This complete assembly of three shelters has been designated as radio set *AN/MRC-2* by the Army. The frequency shift exciter, the control unit, and the dual diversity converter comprise radio teletype equipment *AN/TRA-7*. Figure 19 shows an experimental model of the frequency shift exciter. The converter equipment, shown in Figure 17, is quite similar to the Army converter being provided in the *AN/TRA-7* equipment. The control unit, not shown, is housed in a cabinet approximately the size of the exciter.

Figure 18. Assembly of frequency shift radio equipment (radio teletypewriter equipment *AN/TRA-7*) with teletypewriter apparatus and radio set *SCR-399-A* to provide signal corps radio set *AN/MRC-2*

Figure 17. Single channel dual space diversity radio teletypewriter receiving equipments

As indicated on the map, Figure 20, these radio teletypewriter communication systems were very extensive and handled a large part of the total message traffic over many routes. For example, a large network, using the *AN/FGC-1* system, extended from southeastern United States to the West Indies, to the eastern tip of South America, thence across the Atlantic to Africa. Others linked up India, China, New Guinea, and Australia and numerous islands in the Pacific Ocean, Honolulu, and the west coast of the United States. Another *AN/FGC-1* system extended northward and eastward to Newfoundland, Labrador, Greenland, Iceland, the Azores, the United Kingdom, Russia, and Italy.

Looking at the matter broadly, it may be said that the long-haul radio teletype-

Figure 19. Frequency shift exciter, O-39( )-TRA-7 for use with radio set *SCR-399-A*

Figure 20. Long-haul military radio teletypewriter circuits during 1944

Legend: ——Multichannel System

——Frequency Shift Single Channel System

writer systems provided outstandingly reliable, rapid and secret communication facilities which were found by the armed forces and Government officials to be much better suited for providing extensive military communication networks than alternative arrangements. Although each teletypewriter channel usually operated at a rate of only 60 words per minute, whereas some automatic Morse channels operate at much higher speeds, experience demonstrated that as much or more traffic could be handled each day over a single teletypewriter channel as over a single high-speed automatic Morse circuit. This is possible because the new method of transmission is so superior that the teletypewriter traffic flows at a uniform rate hour after hour with few if any interruptions and enciphering and deciphering may be automatic and instantaneous. This is in contrast to Morse methods which require interpreting and typing the received messages.

The successful application of teletypewriters to long-haul radio links permitted the establishment and successful operation of extensive military teletypewriter networks. This is because the long-haul radio links could be operated in the same manner as the short-haul radio links and wire-line circuits with which they were associated. Thus, by the help of teletypewriter tape relay methods, in which messages were stored in perforated tape form and these used to control transmitters on other circuits, teletypewriter networks extending over land and sea and including long-haul radio facilities and American private-line networks, were operated as an integrated military communication system including connections, as required, with certain stations of the *TWX* system. Results were successful far beyond previous accomplishments in overseas transmission of written communications via radio or other means, and perhaps beyond expectations. Favorable and enthusiastic reports were received on the use of these facilities. Our military leaders and government officials depended upon them for communications, including scheduled conferences in which groups separated by thousands of miles passed communications back and forth practically instantaneously.

The following quotations from President Roosevelt's speech to the Congress on March 1, 1945, regarding the Yalta conference indicates the importance of radiotelegraph in handling the communications while en route to and from Yalta and during the conference there. Both Morse and teletypewriter methods were employed.

"Far away as I was, I was kept constantly informed of affairs in the United States. The modern miracle of rapid communication has made this world very small; and we must always bear that in mind, when we think or speak of international relations. I received a steady stream of messages from Washington, and except where radio silence was necessary for security purposes, I could continuously send messages any place in the world. And, of course, in a grave emergency, we could even have risked breaking the security rule."

Future Outlook

Radio teletypewriter methods not only provide direct reading, no delay, point-to-point overseas communications, but also make possible the radio broadcasting of information from a single station to many others and for conferences to be held, including two or more groups of conferees located on various continents and at sea, all communications being on a secret basis. Radio provides means for communication to moving units, and a new radio teletypewriter service to motor cars, airplanes, and other similar vehicles, using special radio transmission features to secure dependability, now is also technically possible. It would therefore seem certain that the radio teletypewriter communication methods developed during the war will be of prime importance in the future because of their efficient use of the radio spectrum, now so restricted, and the advantages of secrecy, speed, and reliability.

Reactance of Large Cables in Steel Pipe or Conduit

WILLIAM A. DEL MAR
FELLOW AIEE

Synopsis: The determination of reactance of large conductors in steel pipes or conduits has not been susceptible of practical computation but is required for estimating the voltage regulation of pipe cable systems. The present paper gives the results of tests made by Electrical Testing Laboratories (ETL) under the auspices of the Insulated Power Cable Engineers Association, on cables from 750,000 to 2,500,000 circular mils. These data have been supplemented by data from other sources, extending the lower limit of size to 4/10 American wire gauge. Empirical formulas have been developed to include all intermediate sizes and spacings. These formulas are based on the principle of deriving a self-GMD (geometric mean distance) from the a-c/d-c resistance ratio, and using an augmented axial spacing to allow for the magnetic effect of the pipe.

THIS is a companion paper to those entitled A-C Resistance of Large Size Conductors in Steel Pipe or Conduit[1] and Problems in the Measurement of A-C Resistance and Reactance of Large Conductors.[2] It relates to data on reactance, that is, positive sequence reactance, obtained simultaneously with those of the former paper and by procedure described in the latter one.

The tests covered three sizes of cable, 750,000, 1,500,000, 2,500,000 circular mils, the last of these with both concentric and segmental stranding.

Paper 48-252, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted June 10, 1948; made available for printing August 17, 1948.

WILLIAM A. DEL MAR is chief engineer with the Habirshaw Cable and Wire Division of the Phelps Dodge Copper Products Corporation, Yonkers, N. Y.

Acknowledgment is made to R. W. Atkinson, Lawrence Brieger, E. H. Salter, Gordon Thompson and R. J. Wiseman for their helpful suggestions and to J. F. McGuire for assistance in preparing this paper.

The stranding of the concentric cables was as follows: 750,000—61 wires; 1,500,000—91 wires; 2,500,000—127 wires.

The reactance data obtained were as follows, all in ohms per 1,000 feet at 60 cycles and applying to one conductor to neutral, the average for the three conductors being given:

Conditions	Table Number
Three conductors in triangular formation in air	I
Three conductors in flat arrangement in air	II
Three conductors in triangular formation in steel pipe	III
Three conductors in triangular formation in steel conduit	IV
Three conductors in flat arrangement in steel conduit	V

Three Conductors in Triangular Formation in Air: Table I, relating to cables assembled in triangular arrangement in air, will be considered first in relation to the formula ordinarily used, which is as follows:

$$X = 0.0529 \log_{10} \frac{D}{\text{GMD}} \qquad (1)$$

where

X = reactance (60 cycles) in ohms per 1,000 feet
D = axial separation of conductors, inches
GMD = self geometric mean distance of the conductor, which would have the following values for the concentrically stranded conductors:
750,000 circular mils, 0.3853
1,500,000 circular mils, 0.5468
2,500,000 circular mils, 0.7090

This formula does not take into account either skin effect or proximity effect, which latter results from the currents in adjacent phases drawing the current centers inward in relation to the conductor centers and thereby reducing the reactance.

Gordon Thompson has suggested a modification of equation 1 which takes into account the skin effect and assumes the proximity effect to be an accentuation of skin effect without axial displacement of the magnetic field. The actual conductor is assumed to be replaced by an annulus of equal outside diameter D_o and of an internal diameter D_i, such that the d-c resistance of the annulus is equal to the a-c resistance of the actual conductor. Then the cross-section of the annulus (copper plus voids) will be

$$\frac{\pi}{4}(D_o^2 - D_i^2)$$

and that of the actual conductor, (copper plus voids)

$$\frac{\pi}{4} D_o^2$$

Their ratio

$$\frac{D_o^2}{D_o^2 - D_i^2}$$

assuming equal proportion of copper and

Figure 1. Ratio of self-GMD (geometric mean distance) to outside diameter of annulus in terms of a-c-d-c resistance ratio K

Table I. Reactance of Three Conductors in Triangular Arrangement in Air

Size, Circular Mils	Spacing Center to Center in Inches: 1.324		1.598		2.198		1.70		2.17		2.07	
	Copper Temperature, Degrees Centigrade: 20	70	20	70	20	70	20	70	20	70	20	70
750,000 concentric	0.0268	0.0270	0.0297	0.0314	0.0416	0.0414						
1,500,000 concentric							0.0240	0.0245				
2,500,000 concentric									0.0228	0.0228		
2,500,000 segmental											0.0251	0.0254

Brieger obtained 0.0292 for 500,000 circular mil cables on 1.23 inch spacing

Note that in all cases except one the 20 and 70 degree figures are within less than 2 per cent whereas the values for 750,000 on 1.598 spacing differ by about 6 per cent. One of them, probably, the 20-degree figure is in error, and it will be omitted from subsequent tables, and the 70-degree figure used.

Table II. Mean Reactance of Three Conductors in Flat Arrangement in Air

Circular Mils	A		B	
	20°C	70°C	20°C	70°C
750,000	0.0318	0.0334	0.0354	0.0354
2,500,000			0.0271	0.0272

A. Cradled as if in 4-inch conduit, 1.324-inch axial spacing.

B. Cradled as if in 6-inch conduit, the 750,000 circular mil cable on 1.324-inch axial spacing and the 2,500,000 circular mil cable on 2.17-inch axial spacing.

Table III. Reactance of Three Conductors in Triangular Arrangement in 6-Inch Pipe

Size, Circular Mils	Spacing Centers, Inches: 1.598		2.198	
	Copper Temperatures: 20°C	70°C	20°C	70°C
750,000 concentric	0.0363	0.0366	0.0458	0.0468

An equivalent curve is given herein as Figure 1. This curve is based on solid annuli, but is nearly correct for stranded. Taking the experimentally determined value of K and deriving

$$\sqrt{\frac{K-1}{K}}$$

the ratio D_s/D_o is read from the curve and D_s derived by multiplying by D_o.

Then

$$X = 0.0529 \log_{10} \frac{D}{D_s} \qquad (2)$$

The reactance calculated by equations 1 and 2 are shown in Table VI in comparison with the measured values. The ratios of the measured to the calculated values are shown in Table VII from which it appears that equation 2 gives better agreement with the measured values. It will be noted also that the values obtained by equation 2 are always less than those obtained by equation 1, which is as it should be, as an annulus must have a lower reactance than a solid conductor of equal diameter.

Three Conductors in Triangular Formation in Steel Pipe or Conduit. The data for 6-inch steel pipe are given in Table III, and for 4-inch to 6-inch conduit in Table IV.

The ETL measurements were made on only three sizes of cable but fortunately, equivalent data were obtained for two other sizes through the kindness of Lawrence Brieger of the Consolidated Edison Company of New York, Inc., and these are studied in connection with the ETL data, giving much better basis for generalizations.

Due to the limited number of tests with different pipe or conduit sizes, no clear picture could be obtained of the influence of pipe size on the reactance. It was, therefore, decided to neglect pipe diameter and find some relation involving only the conductor size and spacing.

Two methods of generalizing these data were tried. One was to obtain self-GMD values for use in equation 2; the other, suggested by E. H. Salter,[9] was to use an empirical increase of spacing in the same equation using the values of K, in air. Mathematically, these two methods would voids in both cases, must equal the a-c/d-c resistance ratio K.

Then

$$\frac{D_i}{D_o} = \sqrt{\frac{K-1}{K}}$$

Referring to L. F. Woodruff's Principles of Electric Power Transmission,[8] a formula and curve are given from which the self-GMD of the annulus, D_s, may be obtained in terms of the foregoing ratio.

Table IV. Reactance of Three Conductors in Triangular Arrangement in Conduit

Size, Circular Mils	Spacing Center to Center in Inches: 1.324		1.324		1.598		1.598		2.198		1.70		2.07		2.17	
	Conduit Diameter in Inches: 4		5*		5		6		6		5		6		6	
	Copper Temperature, Degrees Centigrade: 20	70	20	70	20	70	20	70	20	70	20	70	20	70	20	70
750,000 concentric	0.0331	0.0343	0.0349	0.0372	0.0372	0.0377	0.0370	0.0376	0.0469	0.0468						
1,500,000 concentric											0.0275	0.0286				
2,500,000 concentric															0.0254	0.0258
2,500,000 segmental													0.0291	0.0298		

Brieger obtained 0.0348 for 300,000 circular mils in 4-inch iron conduit and 1.23-inch in spacing.

* This case is exceptional in the great difference between the 20- and 70-degree data and its correctness may be doubted. It is, therefore, omitted from subsequent tables.

Table V. Reactance of Three Conductors in Conduit in Flat Arrangement

Size, Circular Mils	Conduit Diameter, Inches: 4		6	
	Copper Temperature: 20°C	70°C	20°C	70°C
750,000 concentric	0.0408	0.0410		
2,500,000 concentric			0.0298	0.0302

Brieger obtained 0.0468 for 500,000 circular mils in 4-inch iron conduit on 1.23-inch spacing.

Table VI. Comparison of Measured and Calculated Reactances for Conductors in Triangular Formation in Air

Conductor Cross-Section, Circular Mils	Axial Spacing, Inches	Ratio R_{ac}/R_{dc} K*	Reactance, Measured Average of 20°C and 70°C	Ohms Per 1,000 Feet, Calculated Equation 1	Equation 2
750,000	1.324	1.157	0.0268	0.0290	0.0269
750,000	1.598	1.095	0.0314	0.0327	0.0316
750,000	2.198	1.073	0.0415	0.0400	0.0391
1,500,000	1.70	1.513	0.0242	0.0261	0.0234
2,500,000	2.17	1.934	0.0228	0.0258	0.0222

* These are the average of measured values obtained by ETL at 20 and 70 degrees centigrade. They are here carried to one more decimal place than in Wiseman's paper.[1]

appear to be identical, as they occur as a ratio in equation 2. The latter method, however, was found to be both more practical and more universal in its application, as it works equally well with concentric and segmental strandings.

In order to find the empirical increase in spacing, the necessary data are assembled in Table VIII.

This shows, for each case, the conductor diameter D_o, the actual axial spacing D, the a-c/d-c resistance ratio K, and the derived ratio

$$\sqrt{\frac{K-1}{K}}$$

Using Figure 1, the corresponding values of D_s/D_o for an equivalent annulus are taken from the curve. The self-GMD of the equivalent annulus, D_s, is derived from $D/{}_sD_o$ by multiplying by D_o. This is then put in equation 2, with the measured reactance in pipe or conduit and the empirical equivalent spacing D_1 calculated. This spacing, on the average, is 1.27 times the actual spacing. In view of the range in this ratio, we are not justified in using three places of decimals and a ratio of 1.3 will be used.

The reactance of cables in pipe or conduit would, therefore, be obtained by using the a-c/d-c resistance ratio in air, K, deriving

$$\sqrt{\frac{K-1}{K}}$$

and obtaining the corresponding ratio D_s/D_o from Figure 1. D_s would be obtained by multiplying this ratio by D_o, the cable diameter. The equivalent empirical spacing then would be $D_1 = 1.3\,D$ and the reactance would be given by

$$X = 0.0529 \log_{10} \frac{D_1}{D_s}$$

In Table IX, this factor of 1.3 is multiplied by the actual axial spacings and used in equation 2, to derive a value of X. This derived value is shown in the table after the measured value and their ratio is given in the last column. It will be seen that the error does not exceed 5 per cent except for the two extreme sizes, where it is 8 and 10 per cent respectively.

Segmental Cable: The only ETL data on segmental cable were obtained on one size, 2,500,000 circular mils and one spacing 2.07. However, the author was able to contribute data on a 1,500,000-circular-mil cable on 2.90 inch spacing.

The reactance, in both these cases, conforms with the "1.3 formula" used for concentric cable, as shown in Table VIII, cases 10 and 12.

Three Conductors in "Flat Arrangement" in Air: In this arrangement, the conductors were not actually flat but cradled so as to be in the same position as they would be when as flat as possible in a pipe or conduit of the stated size. The rather meagre data are given in Table II and their relation to the values for triangular arrangement in Table X.

It will be noted that in three out of six cases, the ratio of mean reactance for flat arrangement is from 1.19 to 1.21 times that for triangular arrangement. The one divergent case, where the ratio is 1.24, may be due to an error in the 70 degree measurement as this is 5 per cent over the 20 degree value, whereas in all the other cases the measurements at the

Table VII. Ratio of Measured to Calculated Reactances for Triangular Formation in Air

* Tests reported by Brieger on 500,000 circular mil cable give a ratio of 1.19.

two temperatures are substantially identical.

As the ETL tests covered 750,000 and 2,500,000-circular-mil sizes, we may adopt as a working rule, that the average reactance in air, with flat arrangement is 19 or 20 per cent over that in air with triangular arrangement. The reactance in "flat arrangement" alternatively, may be computed, as for a triangular arrangement, using the cube root of the product of the three axial distances. This, however, involves the computation of the major axial distances as the cables lie in the pipe.

Three Conductors in Flat Arrangement in Conduit: Table V gives the available data and Table XI, a comparison of reactances of cables in flat and triangular arrangements. As with cables in air, the average increase of reactance due to the flat arrangement is 19 per cent, but the range is somewhat greater. The

Table XI. Comparison of Flat and Triangular Arrangements in Conduit

Ratio flat/triangular	1.17	1.17

cube root rule given previously applies less accurately to cables in conduit.

General Conclusions: The reactance of three conductors in a magnetic pipe is not capable of accurate determination because the spacing of the conductors and their positions with respect to the pipe are indeterminate and vary along their length. The diameter, the thickness, and permeability of the pipe also are variable. Nevertheless it is necessary to estimate the reactance in order to determine more or less approximately the voltage regulation of the line.

No theoretical method has been developed and no experimental data for large cables have been available.

The present work, while admittedly incomplete, at least gives us what we had hitherto lacked, a general idea of the magnitudes involved. Tests made by Brieger indicate that the random arrangement which occurs in the field gives reactances between those obtained in the laboratory for triangular and flat arrangements, but nearer to the latter, assuming that, in the laboratory tests, the outsides of the cables were touching along their entire length while, in the field, their spacing was random within the limits of the conduit.

The reactance of an actual 3-phase line in pipe or conduit would be calculated as follows:

1. Obtain the a-c/d-c ratio, K, for cables in air for the proper spacing, as given, for example, in Wiseman's paper.[1]

2. Find D_s the self-GMD for the corresponding value of

$$\sqrt{\frac{K-1}{K}}$$

in air, from Figure 1.

3. Obtain the equivalent spacing D_1 by multiplying the actual center-to-center spacing by 1.3.

4. Then X, the reactance in ohms per 1,000 feet for triangular arrangement of cable in pipe, will be

$$X = 0.053 \log_{10} \frac{D_1}{D_s}$$

5. If the cables are not in triangular formation increase this value of X by 15 per cent to allow for the random position of the cables in the pipe. This percentage is derived from the 20 per cent allowance for flat arrangement and Brieger's correction cited previously.

It is hoped that those who have made actual measurements on pipe lines will contribute their data to check this procedure.

Discussion

L. Brieger (Consolidated Edison Company of New York, Inc., New York, N. Y.): The method of calculating the reactance of conductors in air and in iron pipe, as outlined in Del Mar's paper is a satisfactory empirical approach. The following analysis is submitted, therefore, not as a criticism of his method but as an attempt to put at least an approximate theoretical prop under it.

Reactance in Air

The only references to the reactance of large cables with which this writer is familiar are in papers by H. L. Curtis[1] and H. B. Dwight.[2] Curtis' solution, however, has the practical advantage that he has taken the trouble to evaluate his series and to compare them with tests over a wide range of spacings and frequencies. His solution, therefore, can be recalculated at 60 cycles.

In Figure 1 of the discussion, the lower group of curves show Curtis' data in the form of factors with which the reactance of a solid cylindrical conductor, determined by the standard formula, should be multiplied in order to obtain the true reactance of the conductor at 60 cycles. Curtis' treatment is for solid conductors, but it was assumed that his results would be applicable to stranded conductors as well. The reasonableness of this assumption is justified by the agreement obtained with test data as shown in Table I of this discussion.

The interstrand resistance factors k listed in Table II in my discussion of R. J. Wiseman's paper[3] were used to determine the R_{ac} for each cable size in the table. The slight discrepancy between tested and calculated values of the multiplying factor may be due to stranding, or possibly to differences between single-phase and 3-phase conditions. In any case, these differences are inconsequential and, in the opinion of the writer, the curves on Figure 1 of the discussion can be used with confidence for the evaluation of reactance of concentric stranded conductors in air.

Based on the test made on the 2,500,000-circular-mil segmental sector cable, the reactance of such conductors may be calculated on the basis of the standard formula for solid wire without any correction factor.

Reactance in Iron Pipe

Physically the effect of the iron conduit may be visualized as follows:

Judging from the tests made by ETL, and reported by Wiseman, the pipe materials have the magnetic properties of rolled sheet steel with an initial permeability well over 100. For all practical purposes, therefore, the reluctance of the iron conduit is negli-

Figure 1. Chart based on Curtis' formulas

Figure 3. Three phase reactance of cables, triangular arrangement

gible compared with that of air and the conduit may, therefore, be considered as a surface of constant magnetic potential. The flux distribution in the air inside of the pipe is therefore the same as if the iron pipe were removed and in its stead, image conductors were placed at appropriate points.

For a 3-conductor system, there are three image currents spaced from the center of the pipe at a distance $b = R^2/e$ where R is the inside radius of the conduit and e is the distance of the actual conductor from the center of the conduit. This formula and the method in general are analogous to the one used in electrostatics except that the polarities of charge and image are opposite, whereas the polarities of current and its image are the same. See Static and Dynamic Electricity by W. R. Smythe.[4]

The method of images has been applied in electrostatics to the calculation of cable capacitance with limited success because the charges are not uniformly distributed over the conductor surface. Similarly, criticism may be levelled against the image method for the calculation of magnetic fields because of the nonuniform distribution of current and of the finite extent of the conductor area. The formula of image distance assumes that the current is concentrated in a filament. In order to improve the accuracy, therefore, the test results, or the corrected reactances obtained by the use of the charts in Figure 1 of the discussion may be used to determine an effective spacing of the current focus (fictitious point where the entire current may be centered).

Del Mar considers the effect of unequal current distribution as a shrinkage of the current carrying annulus from the inside and retains the actual spacing between conductors. I find that the method of images works much better if the effect of unequal distribution and consequent increase of resistance is considered as a shrinking of a solid conductor. This is not surprising because in reality for large cables at close spacing, the centers of current distribution are shifted towards one another, due to the crowding of the currents in the three conductors. On the basis of the tested or calculated a-c resistance and under the assumption of a solid conductor, a new geometric mean radius (d'_s) is obtained which is put in the standard reactance formula (Figure 1 of the paper) and a new effective spacing is calculated with the use of the reactance for air obtained either from test or from the charts. For example, in the case of 750,000-circular-mil cables spaced at 1.324 inches, the measured a-c resistance was 0.016 ohms at 20 degrees centigrade which is equivalent on d-c basis to a conductor cross section of 665,000 circular mils, hence $d'_s = 0.445\sqrt{CM} = 0.362$ inch.

With the location of the current centers thus determined, the position of the three image conductors is calculated. The formula for the reactance under the influence of all conductors including the images is derived in the Appendix. It is seen that the effect of the iron conduit is equivalent to a change in conductor spacing by a factor which is influenced by spacings of the three conductors with respect to one another and with respect to the pipe. This spacing correction factor contains distances between the conductors and the images and the writer found it quite convenient to take these

Table I

Conductor Size, Circular Mils	Spacing	d/D	Multiplying Factor for Reactance: Tested	Multiplying Factor for Reactance: From Chart

distances off scale-correct drawings. The procedure is illustrated in Figure 2 of the discussion for one of the conductors tested by ETL. On the left-hand side is the disposition of the conductors and the images for one position of the twisted cables in the conduit. On the right-hand side are shown the conditions when the three conductors have been twisted 180 degrees with respect to their position on the left-hand side. Due to the symmetry of the arrangement, some of the distances in the general correction formula are equal, with a corresponding simplification of calculations. Good accuracy is obtained by taking the average of the two correction factors obtained for the positions shown.

For untwisted cables the position on the right-hand side of Figure 2 of the discussion is more probable, and the calculations were made under the assumption that two of the cables are in contact with the pipe. The spacing correction factors for this arrangement are slightly greater.

Figure 3 of the discussion is a composite picture applying to 750,000- and 500,000-circular-mil cables. The solid heavy line is the reactance in air determined by the standard formula, while the dotted line is the corrected reactance due to unequal current distribution as obtained with the help of the factors given on Figure 1. The test points in air are also shown. The agreement is good except in the case of one of the test points at 1.6 inch spacing which Del Mar himself eliminated and two test points at 2.2 inches which lie above the solid line and must obviously be in error. The tests on cables in conduit are shown by the solid symbols and the calculated reactances using the image method are given by crosses. Good agreement between tests and calculations is evident except in the case of the 1.3-inch spacing, but the writer is inclined to accept the calculated point as more representative because of the too large variation of reactance with temperature, and also because the reactance in the larger conduit was found to be larger which is contrary to theory. The calculations and tests on the 500,000-circular-mil cables are in excellent agreement.

Another way to illustrate the value of the method is to compare the space correction factor as obtained by calculations and from the tests. These are given in Table III of the discussion for all tests on triangular configuration. The reason for the discrepancies in the case of 750,000-circular-mil cables was already noted. Additional evidence regarding the usefulness of the method is given by the good agreement in the case of 1,500,000- and 2,500,000-circular-mil cables.

No claim is made that the image method as simplified for practical application is exact, yet it appears to be a reasonable, simple and straight-forward way to calculate the reactance in iron conduits for all practical cases of triangular configuration.

In conclusion, the field test data given in Table II of this discussion are added to the treasure house of information on the reactance of cable in random dispositions. The field tests on 1,500,000-circular-mil cable, compared with item 10 of Table IX in Del Mar's paper, indicates a 20 per cent increase for random disposition.

W. A. Sinclair (The Detroit Edison Company, Detroit, Mich.): Del Mar, Salter, Wiseman, and the Insulated Power Cable Engineers Association have made a very valuable contribution to the data required for determining ratings of pipe-type cables.

Results of a series of tests conducted on the 35,130-foot Delray-Warren line of the Detroit Edison system provide an excellent opportunity to determine the reactance of 600,000-circular-mil conductors in a steel pipe, with random arrangement. This 120-kv high-pressure gas-filled cable line consists of three SMD-type single-conductor cables installed in a $6^1/_2$-inch inside diameter by 1/4 inch wall, mild steel pipe. The concentric-round conductors are insulated with 600-mils preimpregnated paper over which is a bronze tape intercalated with saturated cotton tape, cotton webbing tape lapped and two half-round copper skid wires 200 by 100 mils applied open spiral, double start. The diameter over the skid wires is approximately 2.315 inches which means that for this line 38 per cent of the pipe is occupied.

Before circulating any current in the conductors, the d-c resistance of the total cable was measured by means of a portable Kelvin double bridge. This value, along with measured temperatures, was used as a reference value for all conductor temperature computations.

Test current for the positive sequence impedance measurements was supplied by six 500-kva transformers connected to give an open-circuit phase-to-ground voltage of about 1,290 volts. Table IV of the discussion gives the impedance values obtained with 530 amperes along with the respective calculated values of resistance and reactance, and the data show the influence of cable temperature on the reactance to be negligible, and at 70 degrees centigrade the 60-cycle reactance was found to be 2.2 times the a-c resistance.

William A. Del Mar: Brieger's theoretical treatment is a valuable contribution to the subject serving to check the consistency of the experimental data and both to interpolate and extrapolate for conductor sizes and spacings not included in the tests. The conception of the steel pipe as a surface of "constant magnetic potential" and therefore as a mirror of the cables in the pipe, is particularly valuable.

The test data given both by Brieger and Sinclair give values of reactance of cables installed in pipe which check quite well, that is within 3 per cent with those calculated by the formulas in my paper for random arrangement, assuming axial spacings, for the triangular arrangements, equal to the overall diameters. These data are given in Table V of the discussion.

Wiseman's paper does not give a procedure for calculating the skin plus proximity effect factor for segmental cable. The skin plus proximity effect ratio, R''/R was worked out for 1,500,000 circular mils for concentric stranding in air using equations 1 and 2 from the Appendix (Wiseman's paper). The skin effect ratio, R'/R or $f(x)$ for 1,500,000-circular-mil cable from Table XV of Wiseman's paper was subtracted from the former ratio, giving the proximity effect alone. The skin effect ratio for segmental 1,500,000-circular-mil cable was then derived in the usual way by taking that of a concentric cable of 44 per cent of its cross-section. This was added to the proximity effect, as derived above, to obtain the skin plus proximity effect for the segmental cable, given in Table V of the discussion as 1.099.

This value is somewhat lower than shown by actual tests of 1,500,000-circular-mil segmental cable, due, probably, to the empirical method used. When an experimental value is used in the described calculations, the ratio of measured to calculated triangular arrangement is 1.20 as indicated by Brieger, and the ratio of measured to calculated random arrangement is 1.05.

It is of interest to note that while the ETL tests were made on cable without metallic covering, the Brieger and Sinclair tests were made on finished cables with metallic tapes and skid wires. These appear to have no appreciable effect on the reactance.

Polyethylene Insulated Coaxial Cable for Carrier Current Control Circuit

H. B. SLADE
ASSOCIATE AIEE

F. P. WEST
ASSOCIATE AIEE

A POWER circuit consisting of 138-kv single conductor 1,250,000 circular-mil oil-filled cables was recently installed between the Sherman Creek generating station of the Consolidated Edison Company of New York, Inc., and the Dunwoodie substation of the Yonkers Electric Light and Power Company, a distance of approximately 8.1 miles. This underground power circuit connects to a 138-kv overhead circuit at the Dunwoodie substation which continues into upper New York state to Millwood, a distance of approximately 21 miles.

Previous to the installation of the 138-kv underground circuit from Sherman Creek to Dunwoodie, the overhead line from Dunwoodie to Millwood had been operated with carrier current superimposed on the high-tension line. It was necessary to extend the carrier circuit to Sherman Creek, since the underground cable was teed to the overhead line at Dunwoodie without circuit breakers. The underground power cable, which was installed with insulating joints and cross-bonding, could not be used for the carrier current circuit because carrier frequency tests conducted several years ago on a similar underground feeder showed that the decibel losses were too high for this use. Thus, it became necessary to install a separate carrier circuit cable.

The cable for the carrier current circuit is installed in the same underground system with the power cable and terminates at the same stations. A cable of the coaxial type was selected consisting of a number 13 stranded copper conductor, 185 mils of polyethylene insulation, a woven copper braid shield and a 78 mils thickness neoprene outer jacket. The cable connects to transmitting and receiving equipment at Sherman Creek and Dunwoodie stations and the circuit also is tied in with similar equipment at the Millwood substation by way of the overhead power line. The carrier current frequency is approximately 60 kc.

The carrier current circuit is used in conjunction with high speed directional relays which protect the power circuits. Carrier current signals are transmitted to block tripping of the high speed relays when a fault occurs outside of the protected circuit.

Coaxial Cable

With the problem of transmitting carrier frequencies over a number of miles with low loss, the choice of dielectric would naturally be between air (with spacers between conductors such as the Bell Telephone System uses) or solid dielectric. Since the circuit is approximately 8.1 miles in length, it was decided to use solid dielectric coaxial cable as being simpler to install and maintain. Of all the solid dielectrics, polyethylene has the most promise for low-power high-frequency transmission, possessing as it does a dielectric constant of 2.3, a power factor of 0.0005 and having unusually stable characteristics over normal ambient temperature ranges and in the presence of water.

The carrier transmitting and receiving equipment required a cable with approximately 70 ohms characteristic impedance and with an attenuation within specified maximum limits at frequencies from 50 to 150 kc, so that the total losses would be kept within the capacity of the equipment.

Since there existed a more or less standard Army-Navy type which met these requirements, this design was selected. The outer shielding braid or conductor possessed so much lower resistance than the center conductor that for practical purposes, the only factors influencing attenuation at the specified frequencies were the resistance of the center conductor, the characteristic impedance, and the proper termination of the cable.

The outer sheath of neoprene was chosen as a noncontaminating material of known long life because of its resistance to oil, flame, weathering, water, and heat.

Manufacture of the cable required precise extrusion and annealing of the polyethylene insulation. The annealing was accomplished by running the freshly extruded insulated wire through 60 feet of troughs filled with water with a starting temperature of 200 degrees Fahrenheit and ending at 110 degrees Fahrenheit. The resulting insulation was formed tightly around the 7-strand conductor to minimize the possibility of voids. The insulated and shielded conductor was finally sheathed with neoprene which was vulcanized at a low temperature so as not to injure the polyethylene dielectric which softens and flows at 230 degrees Fahrenheit.

Tests on the reels of cable included dielectric strength, 15-kv alternating current for five minutes, to guard against imperfections in the insulation, copper resistance tests to guard against open circuits and as a check on wheel measured footage, and attenuation tests performed by a one-quarter wave length resonant frequency measurement developed by the manufacturer for testing carrier frequency cables.

Paper 48-253, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted June 8, 1948; made available for printing August 17, 1948.

H. B. SLADE is a research engineer with The Okonite Company, Passaic, N. J. and F. P. WEST is an assistant engineer with the Consolidated Edison Company of New York, Inc., New York, N. Y.

The authors wish to express appreciation to C. T. Hatcher, H. F. Lindemuth, E. Rigsat and F. C. La Gioia of the Consolidated Edison Company of New York, Inc. and to E. D. Youmans, F. H. Gooding, E. E. Mc Ilvean and H. A. Giller of The Okonite Company for help in the development of the splicing technique and preparation of this paper.

Figure 1. Joint for polyethylene insulated coaxial cable

Splicing

In planning the joints for the coaxial cable, greater attention was given to the formation of a solid section of polyethylene bonded to the insulation of each cable end, offering no chance for moisture to enter and cause failure or change in characteristics of the cable. Splicing tapes of polyethylene with an adhesive layer were found inferior due to water seepage. A molded joint of wrapped plain polyethylene tapes was chosen instead as having the longest life. For simplicity of molding, a cylindrical mold was chosen, with the same diameter cavity as the cable insulation diameter. This was consistent with factory repair technique in that the repair is the same size as the cable, and capable of withstanding factory test voltage and all other tests. At first, it was considered best to form a silver soldered butt splice of the conductor, but for field work, a split sleeve connector filled with solder was proposed. Most of the splicing development was done using these connectors, but eventually the chance for electrical reflections from frequent and irregularly spaced splices of different surge impedance than the cable proper, indicated a return to a splice of the same dimensions as the conductor. The Consolidated Edison Company developed a split aluminum forming clamp (Figure 1) to hold the conductor ends in position while soldering to effect a strong conductor splice of the same diameter as the conductor. The conductor ends were previously scarfed in a die (Figure 1).

In designing the mold itself, numerous factors were considered, tried, kept or discarded. One of the first facts recognized was that polyethylene has a high coefficient of expansion between room temperature and its flow point, and an even higher coefficient above its flow point. The second fact is that polyethylene remains quite firm up to its flow point and then changes to a very soft plastic above its flow point. Under conditions of pressure, the range of temperature from solid to plastic is very small.

Some rubber compositions of a similar high expansion nature had been molded successfully only after extreme care was taken to clamp the cable further back on firm relatively cool insulation, otherwise the cable would push itself out of the mold. Also, where very soft plastic is present in the center of a mold, it is good practice to hold the cable rigid to prevent eccentricity. After a number of molds were made and discarded in attempts to hold cable in place while trying to make a molded polyethylene joint, a mold almost identical to that shown in Figure 1 was made and splices were attempted using 100-watt 115-volt electric heating elements (controlled by a Variac) imbedded in the center section of each half of the mold. Measurements of temperature showed that at about 60 volts on the electric heating elements, the temperature would be 240 to 250 degrees Fahrenheit in the center section, tapering along the finned section to 150 degrees Fahrenheit at the ends. The small hole in the center section was considered to be about the hottest spot and in it was placed a thermocouple, indicating the temperature on a pyrometer. Although the temperature of 250 degrees Fahrenheit for 15 minutes usually sealed tapes and insulation, any compound flashing from the mold was found to indicate a gas pocket next to the conductor. The gas pockets occurred usually near the ends of the center heating section and were thought to be due to numerous causes, including residual soldering flux, leakage of the mold, and hot spots. Extra care in splicing, and tests on plain insulated unspliced cable eliminated the question of excessive flux, and careful checking of temperatures by surface pyrometers at first failed to show hot spots. The joints made similar to Figure 1 frequently had gas pockets under the original insulation. In an attempt to correct the leakage from the mold as a possible cause, a longitudinal liner of 5-mil tinned copper tape was shaped more than half-way around the cable to cover the joints of the mold. The first successful joints were made this way with no bubbles or gas pockets and with only a slight indication of pushing out at the ends of the mold. The correction of leakage seemed to be the answer, and the rest of the splicing procedure was worked out using copper braid ribbon to continue the shielding, with neoprene and friction tapes over all to complete the sheath covering.

Before ordering molds for the field work, it was decided that a 115-volt a-c power supply was not convenient enough along the cable splicing route to make it a practicable way for heating. Consequently, attempts were made to heat the mold with a torch. Such heating was found to be quite suitable and was proposed in the splicing instructions. Also, the 5-mil tinned copper tape mold liner was found to be too soft for general use and a 5-mil monel tape was found more suitable.

As a means of reducing the high-frequency impedance of the shielding on the finished joint, 5-mil tinned copper tape was laid on the insulation under the wrapped copper braid, since the high-frequency currents would otherwise follow the convolutions of the braid

and result in slightly higher losses at the splice.

Since the joint design was new and involved splicing techniques which were new to the splicers, it was considered desirable to have the splicers first make some joints in the Consolidated Edison splicing school in order to train them, and to remove any possible jointing difficulties before installation in the field.

While molding some of the joints in the school, it was found that blow holes occurred in the insulation within the center portion of the mold and more frequently near the points where the hand-applied polyethylene tape joined the factory-extruded insulation. This was first noticed while experimenting with thin copper strips as gaskets between the mold halves to prevent flashing instead of the cylindrical shaped monel liner used previously. The monel liner interfered with assembling the mold over the insulated conductor and sometimes required considerable time even under ideal working conditions in the school. After molding several joints, with and without the use of the monel liner, it was found that the blow holes were forming in the insulation only when the liner was not used. From this experience, it was concluded that the cylindrically-shaped monel liners not only prevented flashing but apparently smoothed out the heat transfer from the outside to the inside of the mold, particularly at the end points of travel of the torch flame as it was played back and forth on the mold. It was decided that the liner was a necessary part of the design, but in order to facilitate the assembling of the upper half of the mold the liner was cut lengthwise in two halves. This permitted more flexibility in adjusting the position of the liners in order to prevent them from catching against the edge of the mold during assembly. The liners were shaped around a mandrel and were used several times before they needed to be replaced. Since they were only 5-mils thick, the outer surface of the molded polyethylene insulation was not made irregular enough to require smoothing before applying the shield.

The original joint design called for the application of polyethylene tape over the conductor, built up to approximately the diameter of the cable insulation. It was observed while molding the joints that the volume of applied polyethylene in a melted state was important and should be controlled within minimum and maximum limits. If the volume was too small, voids were formed. If the volume was too large, excessive pressure which developed during the heating process forced the cable ends too far out of the ends of the mold. This cable movement exerted too much strain on the conductor which in some cases broke the connection where the two ends were joined together. It was found difficult to control the volume of applied polyethylene by the application of tape since it varied with the way each splicer applied the tape and measured the completed jacket.

In order to more accurately control the amount of applied polyethylene and also to save time in its application, it was decided to experiment with the use of a length of extruded polyethylene from the cable for this purpose. A section of cable insulation was cut from cable that was to be discarded and to a length approximately one-sixteenth inch less than the exposed conductor. A slit the width of two hacksaw blades was cut longitudinally on one side of the section of insulation to permit slipping it over the conductor after the two ends had been solder sweated together. The use of the preformed insulation also simplified the joint further by eliminating the need for penciling the cable insulation. When exposing the conductor for splicing, the insulation was cut circumferentially with a dull hot knife to prevent cutting any of the conductor strands.

Even with a closer control of the amount of applied insulation, the cable moved longitudinally out of the ends of the mold during the heating process. The pressure which developed during the heating of the mold was beneficial in reducing the shrinkage during the cooling process, but in some cases the cable ends moved apart enough to weaken or partly break the soldered joint in the conductor.

To relieve some of the pressure which developed within the mold during the heating process and to reduce the corresponding longitudinal movement of the cable from the mold, a vent was made at the center of the mold. The size of the vent hole was made small enough to permit sufficient pressure to develop to mold the polyethylene properly and at the same time keep the cable movement within safe limits.

The explanation of the necessity for using monel (or tinned copper) tape between the mold and insulation appears to be the better distribution of heat along the center section of the mold. The use of the vent proved that leakage of compound of itself did not cause formation of gas pockets. Apparently, a plain iron mold with bolts, guide pins and fins and heated with electric heating elements or an external flame develops hot spots.

Installation of Cable

Two coaxial cables, one of which is for a future circuit, were installed in one of the 5-inch precast concrete ducts without apparent damage to the cable. In some cases the cable was pulled through manholes and racked without joints.

The joints were made without difficulty but voids were found in the surface of the molded polyethylene in several joints after the molding operation. These joints were cut out and remade. In trying to determine the reason for the voids, evidence pointed to moisture condensed on the inside of the metal mold before its use as a possible cause. The trouble was associated more with damp manholes and where extreme care was not used in wiping the mold with a cleaning fluid just previous to its use.

Tests on Circuit

During the installation of the cable, approximately 2.6 miles of circuit was tested by the Consolidated Edison Company by the voltage drop method. This length, including 24 joints, showed an attenuation of 0.28 decibels per 1,000 feet at 60 kc.

Later during the installation, 3.5 miles of circuit was tested by Okonite engineers for attenuation using a one-quarter wave length resonance method developed during the war for factory testing of reel lengths. The two cables tested in this manner yielded about 0.28 decibels per 1,000 feet at 60 kc, including 28 joints.

Upon the completion of the installation of the cable, the Consolidated Edison Company tested the completed length at 60 kc and determined that the losses were still 0.28 decibels per 1,000 feet. The circuit contained 61 joints.

In comparison with tests made on the cable in the factory, the splicing of the cable did not increase the losses of the circuit.

Conclusion

From the field installation and results of tests, it is felt that this type of cable and joint is practical for installation in a conduit and manhole system designed for power cable.

Discussion

L. F. Hickernell (Anaconda Wire and Cable Company, Hastings-on-Hudson, New York): The authors state that "the outer sheath of neoprene was chosen as a noncontaminatory material of known long life because of its resistance to oil, flame, weathering, water, and heat." Also, that "the insulated and shielded conductor was finally sheathed with neoprene which was vulcanized at a low temperature so as not to injure the polyethylene dielectric which softens and flows at 230 degrees Fahrenheit."

In view of the difficulty of obtaining adequate vulcanization of neoprene at low temperatures, the question arises as to why neoprene was selected in preference to polyvinylchloride (a plastic which requires no vulcanization). As is well known, this material is used extensively by the Army and Navy for noncontaminating jackets for similar types of cable.

M. W. Ghen (Duquesne Light Company, Pittsburgh, Pa.): This paper by Slade and West is of timely interest. While it deals only with the splicing of a single type of small control cable, it indicates the difficulties encountered and impresses the engineer with the fact that what appeared to be a simple operation turned out to be quite complicated. Whether or not such difficulties are to be multiplied in proportion when the method is tried on larger cables remains to be seen.

With the increased use of plastics, rubber, and rubber-like compounds, there is room for research into splicing techniques. Any method which results in a splice as nearly like the cable itself as possible is worthwhile. It would appear that the authors have at least pointed the way to the development of satisfactory field splicing of the types of cable mentioned.

The reference to the training of cable splicers and the subsequent difficulties encountered, proves the wisdom of thoroughly instructing field forces in new methods even though study engineers may believe that the procedure has been reduced to a relatively simple process.

The authors are to be complimented upon their thoroughness in solving this problem.

William A. Del Mar (Phelps, Dodge Copper Products Corp., Yonkers, N. Y.): The design of joint described by the authors illustrates both the advantages and the difficulties encountered in the use of polyethylene insulation. A joint integral in material and structure with the cable insulation, such as theirs, is certainly desirable, but it is questionable whether it is practicable for cables of a size much larger than that described in the paper.

Not only are the expansion and contraction difficulties accentuated as far as bubbles are concerned but, as the joint cannot be annealed, as is necessary in making the cable, it will carry internal stresses which are likely to cause trouble under operating conditions.

The use of neoprene compound instead of a noncontaminating vinyl plastic seems like experimenting where a vast amount of operating experience is available. What assurance have the authors that the neoprene compound is noncontaminating? The Geon type of vinyl plastic, as used on Army and Navy high-frequency cables, would seem to be the logical sheath material.

H. B. Slade: The choice of the outer sheath for the carrier current coaxial cable was made primarily on its noncontaminating nature and its long-time operating experience. The difficulties of vulcanizing the neoprene at a low temperature were not a great problem and data in the manufacturer's laboratory indicated that a noncontaminating polyvinyl chloride-type sheath was more permeable to water than a low temperature vulcanized neoprene sheath.

It is well recognized by the authors that a joint made in larger cables might not be as suitable as the type developed, but it was considered that the cable in question operating as it does at a low voltage would not suffer from any slight irregularity in the completed joint. The insulating wall on the cable is heavier, not for purposes of dielectric strength, but to obtain the proper surge impedance for the carrier current circuit.

Insulator Surface Contamination

H. A. FREY
MEMBER AIEE

ONE OF THE major unsolved problems in the insulation of electric power lines is that of obtaining trouble-free operation under conditions of severe atmospheric contamination. This is a problem which has faced the industry for many years. Recently, because of expanded industrial activity, the difficulty seems to be growing in magnitude. Despite the importance of the problem, there is no known general solution. In some particular areas, successful operation has been obtained by periodic washing, by over-insulation, or by the use of special insulators. None of these things, however, can be regarded a general satisfactory solution which can be universally applied.

It is the intent of this paper to outline the problem and to show how the characteristics of insulators are affected under extremely dirty conditions which are probably approaching the worst limit of conditions encountered in service.

The Effects of Surface Dirt on Insulators

The presence of conducting films on the surface of outdoor insulators subjected to high voltages leads to a number of very serious operating conditions. These may be briefly summarized as follows:

1. *Leakage Currents.* If the surface of the insulator were completely coated with a conducting film, leakage currents would flow between the line and ground, and the magnitude of these currents would be inversely proportional to the total resistance of the film. In practice, the surface need not be completely coated with the conducting material in order to permit the passage of leakage currents of serious magnitude. If some narrow bands remain nonconducting, local sparks form through the adjacent air gap, thus shunting the leakage currents past the high-resistance zone. If leakage current is severe, it may result in the charring of wood insulator pins or wood cross arms and the hazard of pole top fires.[1]

2. *Flashover.* The presence of a conducting surface film on an insulator invariably results in some distortion of the voltage gradient over the insulator. Even if the surface film were of uniform resistivity, the resistance of the leakage path would vary due to the hoods, corrugations, and other contours of the surface. Actually the surface is seldom uniformly dirty or uniformly moist so that large variations in the surface resistance may be expected between different zones on the surface of any one dirty insulator. Those zones having the highest resistance are of course subjected to the highest voltage gradients. If the voltage across any one zone becomes high enough, the air gap in parallel with that zone will breakdown forming a local spark. Figure 1 shows such local sparks forming on a dirty insulator under test. These local sparks further distort the gradient over the surface, and the stress concentration at their extremities tends to promote growth of the spark. If several such sparks occur simultaneously on the same insulator, there is a hazard of flashover and loss of service.

3. *Puncture.* The local sparking which occurs over the surface of dirty insulators results in considerable surface heating. If the combination of local voltage gradients and local temperature rise is sufficient, there is danger of puncture of the insulator. Under such conditions, puncture may be caused either by thermal cracks set up by intense local heating and differential expansion, or by the increase in the temperature of the dielectric material itself above its safe operating point. As the temperature rises, the resistance of most insulating material rapidly diminishes. Hence leakage currents begin to flow through the material itself. This results in more energy dissipation and more heating until ultimate breakdown occurs.[2] It is quite probable that insulator failures from this cause in dirty areas are more frequent than is generally realized.

4. *Corrosion.* As a result of operation in dirty areas, greatly accelerated corrosion of metallic parts immediately adjacent to the insulators has been observed. This corrosion may be occasioned by any of several actions. In the first place, under some conditions, the leakage currents which flow through the conducting film may exhibit directional properties so that some electrolytic effects may be observed at the terminal electrodes.

Also, in cases where violent corona or local arcing occur, the formation of ozone and nitric acid may accelerate corrosion immediately adjacent to the insulator. This is particularly possible in cases where the metallic elements affected (for example, insulator pins) are shielded from air currents which would remove the products of decomposition of the air.

A third cause of localized corrosion may be heating. Again in places where the metallic elements are shielded from air currents, local heating, due to leakage currents and sparking may considerably accelerate normal corrosion rates.

Perhaps one of the most common causes

Figure 1. Local sparking on a dirty wet insulator

Figure 2. Corrosion around the pin of a suspension insulator after 17 years service in a contaminated atmosphere

of localized corrosion is the burning effect of the arcs themselves. When localized sparking occurs over a long period of time and terminates on one of the metallic electrodes, the galvanizing at the surface is damaged or destroyed, exposing the base metal to the normal corrosive action of the atmosphere. Some cases have been observed on suspension insulators where corrosion of the insulator pins at the cement line has been so severe as to cause bursting of the insulators. Figure 2 shows the products of corrosion around the pin of a standard suspension insulator which had operated in a contaminated atmosphere for about 17 years.

We may then summarize the effects of dirt on insulators as follows: leakage currents, with consequent hazard of wood burning; power flashover; insulator puncture; and corrosion of adjacent metallic parts.

Types and Quantities of Dirt Which Cause Trouble

There is probably no operating area where outdoor insulators are not subjected to some surface dirt to a greater or lesser degree. This is well recognized, and all insulator designs are prepared with this in mind. Difficulties are not encountered until the dirt concentrations on the surface become very severe, or until abnormally conducting dirts are encountered. In general, any conducting material deposited on the surface of an insulator will affect the insulator performance to some extent. The dirts commonly experienced in the United States have little effect on the performance of insulators so long as the surfaces are dry. Salt, soot, cement, and most of the industrial dirts cause no serious problem so long as they are dry. As soon as such materials are moistened, however, some phases of the dirt go into solution to produce a conducting film. In the presence of large quantities of water, the conducting elements are often quickly leached out, and the dilution of the solution is so great as to produce relatively low conductivity. Hence serious troubles are not often experienced during heavy rain storms. Likewise in areas where heavy rains are frequent, the insulator surfaces are usually automatically washed, and the conducting phases leached away so that trouble is relatively rare. The worst conditions are usually experienced in the presence of fogs, mists, and light drizzly rains. Under such conditions, moisture is provided to produce conducting films on the insulator surfaces, and yet the quantity of moisture present is not sufficient to seriously dilute the solution, or to wash off or leach away the conducting elements. These conditions are usually at their worst when the rain or fog occurs after a relatively long dry spell, during which period, quantities of dirt have had an opportunity to accumulate on the surface.

From this we would expect that the worst kinds of dirt which could be experienced would be those containing a high percentage of soluble matter. This is quite well borne out in practice. Thus, ordinary sodium chloride is extremely severe. Common industrial dirts which contain high percentages of soluble salts, such as fly ash, railroad soot, cement dust, phosphates, and so forth, are very severe, while they remain on the surface. Some of these materials which are almost 100 per cent soluble, such as sodium chloride, will quickly wash off unless they are bound by other inert materials which cake on the surface. Practically all dirts which accumulate on insulator surfaces are a mixture of a number of things. They may consist of fly ash, soot, salt, or other active materials, mixed with relatively large quantities of ordinary wind-blown soil and dust which bake on the surface and influence the washing action of the soluble components.

In addition to retarding the rate of washing, the inert materials also tend to increase the thickness of the water film on the surface. In other words, because of their capillary action they act like blotting paper in maintaining a thick water film on the surface. By increasing the thickness of the water film, they reduce the resistivity of the leakage path and render the operating condition more serious.

Those dirts which have great cementacious properties are, of course, most serious. Portland cement dust, for example, will tend to build up on the surface, layer after layer, to a thick crust, which is firmly bonded, and which cannot be washed away. Other materials, such as some of the phosphates, exhibit this same property. Very often, industrial or railroad smoke carries with it bituminous compounds which firmly bond the other phases of the dirt to the surface of the insulator.

Also many of the commonly experienced dirts are quite hygroscopic so that they are seldom entirely dry. Ordinary sodium chloride is of course very hygroscopic, and Portland cement exhibits this property to a considerable degree. The dirt accumulation on insulators is seldom static for any considerable period of time. It is constantly being built up by the deposit of additional material and washed or leached away by the action of wind and rain. The quantity of dirt present on the surface of any particular insulator therefore will be controlled by:

1. The rate of deposit of dirt.
2. The frequency and intensity of washing rain and wind.
3. The nature of the dirt, that is, its ability to cake and bond to the insulator surface.

The Resistance of Dirt Films

As pointed out previously, most of the commonly experienced dirts are seriously conducting only in the presence of moisture. The conductivity is due to the solubility of the dirt and the formation of low-resistance electrolytes. The resistivity of most electrolytes is inversely proportional to the number of parts per million of soluble matter in solution. For the same solution concentration, the resistivity of most electrolytes will be influenced also to some extent by the molecular weight of the salt which is in solution. Salts of high molecular weight will generally produce electrolytes having high resistivity and vice versa. In practice, the variations in resistivity due to solution concentration greatly outweigh those due to the nature of the particular salt which is in solution.

The resistance of the surface film on any circumferential element of a dirty insulator will be directly proportional to the product of the resistivity of the dirt and the length of the element, and will be inversely proportional to the cross-sectional area of the dirt film at that element. The cross section of the dirt film is in turn the product of the thickness of the film and the circumference of the element. The resistance from point to point in the leakage path over the surface of a dirty

insulator will therefore vary with the resistivity of the dirt, the thickness of the dirt film, and the circumference of the insulator at those points. It is this variation in surface resistance from point to point which results in the distortion of voltage gradient.

The resistivity of the dirt film on insulators in service varies over a wide range. In some areas, the coatings must build up to considerable thickness before trouble results. Other types of dirt may cause serious trouble when the thickness of the film is so small as to be almost invisible. A typical example of the latter is nitrated cotton lint.

Some idea of the relative severity of different types of dirt can be gained from a simple test. A weighed sample of the dirt is mixed with a measured quantity of distilled water, the mixture is filtered, and the resistivity of the filtrate measured. This produces an arbitrary measure of the relative severity of that particular dirt in the presence of moisture. In Table I are listed the results of measurements of this type made on several commonly experienced dirts. One of the questions which is always involved is the speed with which the conducting agents are leached out of a particular dirt. This provides some information on the speed of cleaning during normal rains. Some measure of this can be obtained by taking the residue of dirt which has been filtered out of the first mixture, remixing in the same proportions with distilled water, again filtering, and measuring the resistivity of the filtrate.

The change in resistivity of the filtrate from the second mixing gives some idea of the speed of leaching for the particular dirt. Table I includes the results obtained by remixing the residue from the first test. It was, of course, impossible to remix the residue of cement since it had set after the first trial. In these tests flint was included as the control since it is generally regarded as a relatively insoluble material. However, it should be noted that even commercial flint contains sufficient soluble matter to appreciably effect the resistance of distilled water which was used in the mixture. The initial resistivity of the distilled water before mixing was more than 150,000 ohms per centimeter cube. After the first mixing the resistivity of the solution which has been in contact with the flint was reduced to 21,000-to-23,000 ohms per centimeter cube. It should be noted that the fly ash used in these experiments had been taken from the collectors of a power plant where it had been hosed down to control dust. Hence, it is quite probable that some of the soluble matter had been leached out before the test sample was obtained.

This method of investigation may have practical value in estimating the severity of the dirt encountered in particular locations.

Laboratory Flashover Tests

For many years laboratory tests have been made by operating companies and by insulator manufacturers to study the performance of insulators under dirty conditions, and to compare the relative performance of various insulator designs. All laboratory tests of this nature are limited in their simulation of actual operating conditions. The results of the tests will be influenced by the quantity and nature of the dirt used, by the degree to which the surface is moistened, and by the distribution of the dirt and moisture pattern on the surface of the insulators. In service, where insulators are continuously energized, the actual pattern of distribution of the dirt on the surface may be controlled by the voltage gradient around the units, as well as by the washing and eroding action of rain and wind. It is very difficult to be sure that a laboratory test truly represents the operating condition which would exist after months of exposure in a particular location. The results of such tests must therefore be used with caution.

Despite their limitations, laboratory tests can furnish much valuable information when properly used. Such tests have been made by a variety of methods. In some cases, the insulators under test have been placed in closed chambers into which salt mists have been injected. In other cases, the insulator surfaces have been artificially coated with dirt and then moistened by mists or light sprays of water. By making the test very severe, some idea can be obtained of the performance of insulators under the worst operating conditions which are probable.

With this in mind, a number of tests have been made on insulators of various types and sizes. Pin-type insulators, switch and bus insulators, and suspension insulator strings were included in the test. Both fog-type and standard suspension insulators were used. Post-type insulators were included among the various pin-type and switch insulators. The entire surface of each unit was coated with a mixture of salt and kaolin. This "dirt" was applied by spraying the surface with a concentrated solution of salt (sodium chloride) in water. The moistened surfaces were then dusted with powdered kaolin and allowed to dry. This process was repeated to build up, layer by layer, a heavy surface coating. Coatings of this type are very severe. The salt is readily soluble and so quickly produces a low resistance electrolyte in the presence of moisture. The kaolin acts as a binder to retard the removal of the salt during the process of testing and to increase the effective thickness of the moisture film.

After the application of the final layer of salt and kaolin, the insulators were placed in a dense mist of fine water drops, as produced by atomizer-type spray guns. The mist was directed so as to wet all surfaces of the insulators. Under these conditions, the 60-cycle flashover voltage was measured. Then the same insulators, still dirty, were placed in a light spray of water directed downward at about 45 degrees from the vertical, and simulating a light rain. The 60-cycle flashover voltage was again measured. In Figure 3, the lowest measured flashover voltage for each insulator tested is plotted against the insulator size as measured by its dry arcing distance. As would be expected, the test points fall within a band of considerable breadth. The breadth of this band is effected more by variations in the test than by variations in insulator types.

Table I

Kind of Dirt	Weight of Dry Dirt, Grams	Quantity of Distilled Water, Cubic Centimeters	Resistivity of Filtrate, Ohms Per Centimeter Cube	Approximate Parts Per Million in Solution
First Mixture				
Flint	5	50	21,000–23,000	28
Fly ash	5	50	1,930	320
Blast furnace	5	50	1,300–8,900	450–70
Railroad soot	5	50	592	1,000
Cement	5	50	236	2,500
Second Mixture				
	Using Dry Dirt Residue From First Mixture			
Flint	4.919	49.19	35,000–37,000	16
Fly ash	4.947	49.47	13,300	45
Blast furnace	4.916	49.16	5,000	120
Railroad soot	4.870	48.7	1,450	400
Cement				

In other words, the band may be used as a rough measure of the probable flashover voltage of any practical insulator under very severe service conditions. The clean-dry and clean-wet 60-cycle flashover voltages of the same insulators are plotted as bands in Figure 3 for comparison.

The great reduction in 60-cycle flashover occasioned by surface dirt makes it very difficult to find the relatively small differences which may result from variations in insulator design.

The same data is plotted in Figure 4 as a function of leakage distance. The breadth of band so obtained is even greater than when plotted against arcing distances. This reflects the loss in efficiency of leakage distance which is so often observed on insulators having a high ratio of leakage distance to arcing distance.

It is believed that, in general, the data summarized in Figures 3 and 4 are fairly representative of very severe operating conditions. As verification of this, a typical insulator was secured which had been in service in a very badly contaminated area near a chemical plant. This insulator was heavily coated with phosphates and miscellaneous industrial dirt, and represents an extreme practical condition.

It was tested with a minimum disturbance of the surface coating and the measured flashover voltage is plotted as a cross on Figures 3 and 4. Note that it falls within, but towards the bottom of the laboratory test band.

In the interpretation of laboratory flashover tests on dirty insulators, it is important that the element of probability be considered. Flashover on an insulator may be initiated by the chance simultaneous formation of several local sparks on different parts of the surface. The probability of this occurring on one insulator during the brief period of one test may be very remote. However, in service, with hundreds of insulators involved and for considerable periods of time, the probability of such an occurrence on some one unit is much greater. There is also the possibility that on continuously energized insulators in service, the heating and drying action of leakage currents will modify the flashover characteristics to some degree.

Figure 4. Sixty-cycle flashover voltage of dirty insulators of various types and sizes plotted as a function of leakage distance

Figure 3. Sixty-cycle flashover voltage of dirty insulators of various types and sizes plotted as a function of arcing distance

Leakage Currents

To give some idea of the variations in leakage current which may occur across insulators under a variety of surface conditions, a number of laboratory measurements have been made. Figure 5 shows the variation in leakage currents experienced on a typical pin-type insulator of a size commonly used on 34.5-kv circuits. This type of insulator is illustrated in Fig. 6. The measurements on clean insulators were made with direct current in order to detect the small leakage currents which would otherwise be masked by the relatively large charging currents. Note that under dirty conditions in a mist, the leakage currents are of the order of one million times those which flow over a clean-dry insulator. Furthermore, in this particular case, no leakage measurements could be made on the dirty-wet insulator at voltages above 25 kv because at higher levels local sparking became severe, and variations in leakage current were so large and so rapid as to be unmeasurable by the method employed. Above 25 kv, some of the peaks of leakage current may have been ten times the level indicated by extrapolation of the lower test points.

With variations in leakage current of this magnitude, it is futile to try to control them by methods which are capable of changing the resistance of the leakage path by only a few per cent. Leakage currents can be effectively controlled only if some parts of the insulator can be kept relatively clean or relatively dry. Even then the clean or dry areas must be paralleled by an air gap which is wide enough to support the voltage without breakdown. If under the existing conditions, this cannot be accomplished, then steps must be taken to prevent burning of wood members by partially or totally bonding them with wire or metallic strips.[1]

Impulse Flashover

It has been considered generally that the impulse flashover of insulators would not be seriously affected by surface dirt. It is true that the impulse flashover of dirty insulators is not reduced as much as is the 60-cycle flashover. There is, however, an appreciable reduction in the

Figure 5. Leakage currents for a typical pin-type insulator under various conditions of surface contamination

Figure 6. Typical pin-type insulator commonly used on 34.5-kv circuits

critical impulse flashover voltage. Figure 7 shows the result of impulse flashover tests on dirty $5^3/_4$-by-10-inch suspension insulators, using a $1^1/_2$-by-40 microsecond wave. The two upper curves show the critical impulse flashover voltage of clean dry insulators. The test points scattered along these two curves are the impulse flashover voltages measured on dry dirty insulators. The scattered points in the lower band are the measured impulse flashovers of dirty insulators in a fine mist of water. The variations in individual tests were quite wide, as indicated by the breadth of the band in Figure 7, and were too great to detect any significant difference between positive and negative wave values.

These impulse tests were made with the insulators coated with salt and kaolin, as described previously, and also with the insulators sprayed with a salt water mist. Since it takes an appreciable period of time to make one impulse flashover measurement, there is considerable washing action during the process of the test. It is, therefore, difficult to be sure that the degree of contamination remains the same during the test. Hence, even though an attempt may be made to produce a dirt film at the beginning of the test which approximates very severe service conditions, it is possible that the actual condition tested may be less severe. The values shown in Figure 7 may therefore be an optimistic estimate of those experienced under the worst probable service conditions.

This reduction in impulse flashover due to surface dirt may sometimes have to be considered in the selection of insulators to meet required basic insulation levels.

Conclusions

1. For operation in dirty areas, the most important consideration is the size of the insulator. Insulators, not one, but several steps larger than normal are often required. For example, it is not at all uncommon to use 34.5-kv or even 46-kv insulators on 13-kv circuits in dirty areas.

2. All American standard insulators are made with surface contamination as one of the major design factors. For most applications, in dirty areas, the best balanced insulation will be obtained by the use of standard insulators of adequate size. There are cases where the use of standard units of adequate size becomes impractical due to clearance limitations or to other local conditions. In these cases, special designs, usually called fog-type insulators, may be required.

3. In dirty areas, wood members should be bonded, and conducting insulator pins should be used to prevent burning.

4. In very dirty areas, it may be necessary to wash insulators periodically[3] in order to maintain service.

5. Impulse flashover voltages may be seriously affected by surface dirt. This influences the ability of insulators to meet required basic insulation levels in service.

6. Predetermination of the proper insulation level is at present almost impossible except through experience with a particular exposure. There is no yardstick to measure

Figure 7. Impulse flashover of dirty $5^3/_4$-by-10-inch suspension insulators

the severity of conditions in any location. The factors entering into such a measurement are:

a. The rate of deposit of dirt.

b. The nature of the dirt—its relative conductivity and its bonding properties.

c. The frequency and intensity of rain and wind.

There is real need for a study of these factors to establish a relative measure of exposure severity and to permit intelligent predetermination of required insulation levels.

Discussion

Grover W. Lapp (Lapp Insulator Company, Inc., LeRoy, N.Y.): This paper and three others contributed to this symposium on insulator contamination, present a useful summary of the work that has been done for the past several years on the basis of which we may expect further progress in insulator design and specific application of insulators to service in contaminating districts.

One fact upon which all seem to agree is the beneficent effect of rains or washing in reduction of leakage current and liability to flashover.

The dry insulator seldom gives any trouble. Wetness produces electrolytic conductivity to various degrees as shown by the data. Fortunately, in most cases the conductive ingredient in the contaminated coating is soluble and can be reduced by leaching out. The soluble part of the coating goes into solution when wetted, and, as the moisture dries, a point of concentration is reached at which saturation takes place after which there is a successive deposition of crystals and salts of the various soluble materials, producing a more or less tightly adherent coating cemented to the insulator surface by many wettings and dryings and reduced by wind and weather not readily reproduced in laboratory tests.

So beneficial is water, and especially rain water, in leaching out this soluble conductive adhesive part of the coating that tests reported after artificial washing show a reduction of leakage current to only ten per cent of the value before washing.

There may be instances in which sufficient surface on the insulator can be maintained dry to prevent flashover. Such secluded surfaces are likely to produce bulky designs and are difficult to wash. Even if rain cannot get access to these hidden surfaces, humid air on a cool insulator can condense moisture, and drifting fog can wet them to produce maximum conductivity at critical times during the seasons.

Energy losses help to dry up surfaces at short radius, as around the pin of a suspension insulator, to such an extent as to produce frequent sparking. Unsatisfactory voltage gradients reported indicate this condition.

Insulator manufacturers formerly listed wet flashover distance of pin-type insulators as the sum of the distances from the lip of one shell to the next, plus the radial distance to the pin. At an early stage of voltage rise on a flashover test, these dry gaps spill over and become valueless or even a liability. From that point up, the portions of

wetted path in series with these arclets are the principal elements to prevent flashover. On the other hand, it is difficult to cause flashover along a uniformly wetted path from terminal to terminal. Under ideal conditions this uniform conductive path serves to make the potential gradient more uniform in that locality so that flashover may occur elsewhere.

For these reasons, and in most cases, it is best to plan on uniform wetness of path as a principle of design. Examples of such designs have served well, notably old transformer bushings. In more recent years post-type porcelain insulators having many small externally exposed corrugations have done well in service.

There is some prospect of specific improvement in design for self-conditioning insulators to be used in contaminated atmospheres, so that we may be free from the blanket rule that two inches of leakage distance must be provided per kilovolt of applied voltage.

H. A. Frey: Lapp's comments, concerning the beneficial washing affects of rain, are certainly quite true. We must realize, however, that these natural washing actions require time. When rain water initially wets the surface of a dirty insulator the first action which occurs is detrimental. The moisture takes into solution some of the soluble matter on the surface and forms a rather highly conducting film. The insulator must be capable of operating satisfactorily under these conditions and until the washing action can be completed. For this reason, insulators are provided with hoods or corrugations. These provide additional leakage distance and some protected area which is capable of supporting line voltage until exposed surface can be washed to some degree. The protected leakage surfaces must not be short circuited by narrow air gaps, otherwise the shunting gaps will break down and the value of the theoretical leakage distance is lost. Obviously, the most effective relationship between the length of the protected leakage distance and the length of the shunting air gap is determined in some measure by the physical arrangement of the air gaps. Leakage distance, as measured on paper, is of little value if it is short circuited in service at the time when most needed. Perfectly smooth suspension insulators having relatively low leakage distance but ample spacing have been used with good results under some contamination conditions.

Coupling Capacitors and Traps for Rural Line Carrier

AN AIEE COMMITTEE REPORT

AT THE January 1947 meeting of the Institute, two technical papers[5,6] were presented which described in some detail the design and the method of application of equipment utilized to provide rural telephone service by carrier on power lines. In addition, there have been numerous articles[5,6] describing the system in the technical press. Subsequent to the time these papers were presented, carrier telephone equipment had been installed on rural power systems throughout the country, establishing carrier telephone systems on a commercial basis. This equipment has also been applied to telephone circuits to provide subscriber service and short-haul toll service.

Since the application of the carrier telephone system to power lines involves the attachment of newly developed equipment of special design to primary power conductors, there has naturally been considerable interest evinced in the performance of the equipment in so far as its effect on operation of the power systems is concerned. With this in mind, the carrier current committee of the Institute obtained information on the performance of the carrier telephone equipment which has been installed on power lines during the past year. The purpose of this report is to discuss the performance of this equipment and to provide information on the present status and probable future field of use of the rural carrier telephone system. Since details concerning operation of the carrier system are provided in numerous articles and papers[1-6] only a brief description of the essential features will be included here.

The system operates at frequencies in the 150–425 kc band. Five 2-way channels, each serving up to eight subscribers, can be obtained by utilizing the entire band. The subscriber terminal equipment consists of a carrier transmitter and receiver operated from the 120-volt power service. The handset provided for the subscriber terminal is similar to a conventional handset, and, as far as the subscriber is concerned, the operation of the system is identical to a voice frequency telephone circuit. The common terminal unit is provided to connect the power line carrier section to the central office. It consists of a carrier transmitter and receiver, terminating in an ordinary voice frequency pair which provides the connections to the central office. Each channel used in a carrier section requires a separate common terminal unit.

The system is designed for use primarily on power lines of the multigrounded neutral-type operating at or below 8,700 volts to ground. It can be extended to other types of systems under some conditions. To apply the system to power circuits, it is necessary to provide series chokes to confine the carrier frequencies to the section of power line utilized, and coupling capacitors to couple the subscriber and common terminals to the power circuit. Figure 1 shows a typical layout of a power line modified for carrier telephone service. It can be seen that three types of chokes, having characteristics as shown in Table I are used. The chokes provide the necessary value of impedance at carrier frequencies to isolate or reduce the carrier transmission beyond them, but at the same time their 60-cycle characteristics are such that they have a minimum effect on the operation of the power system. The "isolating" choke is shown in Figure 2. It is mounted in a 2-bushing oil-filled metal container and is protected by gaps to ground and across the coil. It is designed and constructed so as to meet all of the dielectric strength requirements for 15-kv class equipment of ASA-C57.1.[7] The "transmission" and "tap" chokes are designed for mounting on pin-type insulators of the same type as used on the power circuit on which they are applied. Therefore, the dielectric strength to ground is provided by the insulators. Gaps are provided across the coils to by-pass surge voltages. The more important tests to which the chokes are subjected are shown in Table II.

The coupling capacitors presently employed are glass encased, hermetically sealed, mineral oil impregnated, paper dielectric units. Figure 3 shows one of these units. They were designed to meet the requirements of AIEE Standard Number 31[8] and for the 15L rated insulation class. A fuse of low ampere rating is used in the connection of the capacitors to the phase wire.

The capacitors are given extensive tests to insure that they meet requirements. The types of tests and corresponding requirements are summarized in Table III.

Where this is not feasible, the capacitors should be located as near as possible to a transformer pole. For this latter condition, some of the protection afforded by the lightning arrester or gap is sacrificed.

Coupling units are used in the ground side of the capacitor. They provide the 60-cycle drainage to ground and carrier connection to the terminal equipment. The normal 60-cycle voltage drop across the coupling unit is less than one volt. It is protected for abnormal voltages by copper protector blocks which break down at about 1,200 volts.

Paper 48-256, recommended by the AIEE carrier current committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 2, 1948; made available for printing August 19, 1948. This report was prepared for and approved by the carrier current committee. Text and data were prepared by S. C. Bartlett.

Personnel of the AIEE carrier current committee: L. F. Kennedy, *chairman;* S. C. Bartlett, W. H. Blankmeyer, C. W. Boadway, J. M. Dunham, L. C. Eaton, R. C. Ericson, L. F. Ferri, W. J. Googe, K. E. Hapgood, E. W. Kenefake, S. C. Leyland, S. Lubin, L. E. Ludeksna, D. M. MacGregor, T. W. MacLean, R. H. Miller, R. E. Neidig, F. M. Rives, Merle Robison, Trueman T. Smith, Oliver A. Starcke, T. D. Talmage, and Mead Warren, Jr.

The committee desires to express its appreciation for the assistance rendered in the preparation of this report by the chairman and members of the Edison Electric Institute–Bell System Joint Subcommittee on rural telephone service by carrier on power circuits.

Figure 1. Arrangement of equipment on rural power line modified for carrier transmission

The chokes, capacitors, and coupling units are all installed on the poles in accordance with the requirements of the National Electric Safety code for similar power line equipment. Figure 4 shows a typical installation of some of this equipment.

All of the carrier equipment is normally owned by the telephone company. However, all equipment installed on the power line that is attached to the power circuit (chokes, coupling capacitors, and coupling units) is installed and maintained by the power organization. Equipment not connected directly to the power circuit (telephone drops and connections to the coupling units) is installed and maintained by the telephone company.

Field experience to date indicates substantial freedom from maintenance difficulties with the carrier equipment connected to the power line or interruptions to power service caused by it. Up to April 1, 1948, 14 capacitor failures have been reported out of a total of around 4,000 installed. Most of the failures were experienced during the severe lightning season last summer. In all of these cases, the capacitor fuse operated without causing operation of other system protective devices, so no interruptions to power service resulted. Six cases of capacitor fuse failures have been reported which did not involve failure of capacitors. Most of the capacitors which have failed were of the earlier manufacture and since that time test procedure changes have been made which, it is expected, will improve the capacitor performance. Also additional studies and tests of the capacitors and methods of

installation have been initiated which should lead to still further improvement.

Two isolating choke coil failures have been reported, one of which caused an interruption to power service beyond the point where it was installed. The failure occurred in a choke of early manufacture and was traced to a defect in design which has been corrected. Circumstances regarding the other failure have not yet been reported.

Table III

Type of Test	Requirements
Routine Tests	
Dielectric strength	Withstand 18 kv, 60 cycles for one minute
Capacitance (at 60 or 1,000 cycles)	1,950 micromicrofarad minimum: 2,450 micromicrofarad maximum
Insulation resistance	Not less than 10,000 megohms at 25 degrees centigrade
Liquid tightness of container	No visible evidence of leakage after three hours in oven at 75 degrees centigrade
Sampling Tests	
Impulse strength	Withstand 95 kv, $1^1/_2$–40 wave
60-cycle dry	Withstand 35 kv for at least one minute*
Resonance	Tests at 100 and 600 kc to insure that capacitance is between 1,800 micromicrofarad at such frequencies
Radio frequency noise	Free from radio frequency noise when subjected to 10,000 volts, 60 cycles
Life test	Withstand 13,000 volts for 1,000 hours at 65 degrees centigrade
Seal test	Withstand without damage extensive heat cycling and thermal shock tests

*Made on routine basis on earliest manufacture only, later changed to avoid possibility of corona damage on units shipped to customers.

Capacitors of this design have withstood impulse voltages considerably in excess of test requirements. They have also lasted for several thousand hours on accelerated life tests.

While the coupling capacitors are designed to meet the same, or more stringent, dielectric tests than are required for other equipment installed on the power circuits, it is intended that they be installed on the same pole as distribution transformers so as to take advantage of the protection afforded by lightning arresters and/or gaps normally associated with transformers.

Other difficulties with the carrier system have been encountered which did not involve equipment connected to the power circuit. These difficulties include some interference with broadcast radio reception which has been cleared up by minor changes in the design of carrier terminal equipment. There have been some other equipment difficulties which are being given intensive study and it is anticipated they will be corrected in the near future.

The results of operation of the rural carrier telephone system on a substantial number of rural power systems for periods of time ranging from over a year to a few months indicate that the design and construction of equipment applied to power circuits is basically satisfactory. It is apparent that the system no longer is developmental but can be considered and utilized as a practical system in lieu of, or in conjunction with conventional telephone circuit facilities. The field of use of the system in the future will be determined by its relative economy and suitability in comparison to other types of facilities, and will depend on a number of factors which will need to be evaluated in specific situations. It will be most attractive where the prospective telephone customers served by power distribution lines are remote from existing telephone facilities, and where the separation between customers is of the order of one-half mile or more. The relative flexibility of the carrier system deserves particular consideration. When a power line has once been equipped for a carrier section, service can be rendered to any customer within the section up to the ultimate capacity of the system, usually 40, by adding channels from time to time without necessarily making any modifications in the sectionalizing equipment. In the event of discontinuance of service by carrier to a customer or on an entire section of power line, the recovery of original investment in equipment is much greater than in the usual case with conventional facilities.

Report on Method of Measurements at Carrier-Current Frequencies

AN AIEE COMMITTEE REPORT

THE purpose of this report is to outline certain methods of measurement to obtain data for the application of carrier-current apparatus to power lines. The objectives in regard to the data needed have been set down in a report, Study of Power System Characteristics at Carrier Frequencies. This report will be used as a guide as to the desirable data to be accumulated and hence sets the pattern for the type of measurements to be made.

In general, it has been felt desirable by the committee that these measurements should be made over an extended frequency range of 30 to 300 kc, and, wherever possible, data over this wide range should be obtained. Undoubtedly, there will be instances where equipment is not available to cover this wide range and the data for a narrower range will have to be taken. This information will be valuable even though it only covers the 50 to 150 kc range or some other range similar to this.

In investigating this general problem of obtaining data, it becomes quite obvious to anyone that it would be nice to accumulate a large amount of varied information. It is also obvious that if an ambitious program is set up, little may be accomplished. It seems that the field would be served best by information on effect of connected power apparatus and noise levels.

Referring to the previous report on Study of Power System Characteristics at Carrier Frequencies, the following tabulation will give the items referred to in this report and a suggested method for obtaining the data in each case. In this report are five methods of measurements, covered under Part I to Part V inclusive.

A. Substation Equipment

a. Power Equipment. This covers power transformers, capacitor potential devices, instrument transformers, coil circuit breakers, lightning arresters, and bus structures. Information is most desired on the first two items, and this can be obtained by using one of the methods of measurements described in Part I. In other words, if the impedances of these devices are known, their effects on carrier frequencies can be determined.

b. Carrier Equipment

1. Line Traps. Impedance of line traps can be obtained by the method of measurement described in Part II and if more detailed impedance characteristics are required, the method described under Part I may be used.

2. Coupling Capacitors. The impedance of coupling capacitors can be measured by the method described in Part I to yield information on power factor. This measurement should be made with and without protective equipment connected, and the high-voltage side of the capacitor should be grounded in the setup so that the low side will be at high (radio-frequency) potential simulating the actual usage of the capacitor.

3. Line Tuning. The pass band characteristics of line tuning unit can be obtained by the method of measurement described in Part III and may be for a simple or a complex tuning unit.

c. Complete Substations. It would be interesting to obtain transmission characteristics on complete substations by the use of the method in Part III. However, it would be just as desirable to measure the impedance of the substation by the method described in Part I.

B. Transmission Lines

a. Depending upon the circumstances, either by the method described in Part III which is applicable to long lines, or the method described in Part IV for short lines, the impedance and attenuation should be measured on certain typical lines and cables. This should bring out the effect of ground wires and differences between various phase wires.

b. More information is needed on the voltage distribution among the phase wires when coupled phase-to-ground and interphase. Information on the field strengths in the vicinity of power lines for interphase and phase-to-ground connection would be desirable.

Part I. Method of Measuring Unknown Impedances Which Contain Reactance and Resistance

General

In order to measure impedances of various kinds of connected apparatus to power transmission lines, it is expected that these impedances will involve both reactance and resistance, and the methods described subsequently will give desirable schemes for measuring these kinds of impedances. In general, the problem of measuring an unknown impedance can be done by a Q-meter or an r-f bridge, but, because there seems to be no suitable r-f bridge, the Q-meter method will probably have to be used. This method is described in detail in the instruction book for Boonton Q-meter[1] for measuring an unknown impedance and need not be duplicated here. In very many cases, a Q-meter will not be available but the principles of this type of measurement can be used. Certain liberties can be taken because of the low frequency range, and a method can be used which uses equipment generally found around carrier-current installations. Therefore, when a Q-meter is not available, unknown impedances can be measured with the following equipment:

1. Carrier-current transmitter or r-f generator.

2. Resistors.

Paper 48-257, recommended by the AIEE carrier current committee and approved by the AIEE technical program committee for presentation at the AIEE Midwest general meeting, Milwaukee, Wis., October 18-22, 1948. Manuscript submitted August 2, 1948; made available for printing September 10, 1948.
